Markov Chain Monte Carlo Data Association
for Multi-Target Tracking

Songhwai Oh, Stuart Russell, and Shankar Sastry

Abstract

This paper presents Markov chain Monte Carlo data association (MCMCDA) for solving data association problems arising in multi-target tracking in a cluttered environment. When the number of targets is fixed, the single-scan version of MCMCDA approximates joint probabilistic data association (JPDA). Although the exact computation of association probabilities in JPDA is NP-hard, we prove that the single-scan MCMCDA algorithm provides a fully polynomial randomized approximation scheme for JPDA. For general multi-target tracking problems, in which unknown numbers of targets appear and disappear at random times, we present a multi-scan MCMCDA algorithm that approximates the optimal Bayesian filter. We also present extensive simulation studies supporting theoretical results in this paper. Our simulation results also show that MCMCDA outperforms multiple hypothesis tracking (MHT) by a significant margin in terms of accuracy and efficiency under extreme conditions, such as a large number of targets in a dense environment, low detection probabilities, and high false alarm rates.

I. INTRODUCTION

Multi-target tracking plays an important role in many areas of engineering such as surveillance [1], computer vision [2][3], network and computer security [4], and sensor networks [5]. In the standard setup, some indistinguishable targets move continuously in a given region, typically independently according to a known, Markovian process. Targets arise at random in space and time, persist for a random length of time, and then cease to exist; the sequence of states that a target follows during its lifetime is called a track. The positions, or more generally partial states, of moving targets are measured, either at random intervals or, more typically, in periodic scans that measure the positions of all targets simultaneously.

Songhwai Oh is with Electrical Engineering and Computer Science, University of California, Merced, CA 95344. songhwai.oh@ucmerced.edu. Stuart Russell and Shankar Sastry are with the Department of Electrical Engineering and Computer Sciences, University of California, Berkeley, CA 94720. {russell,sastry}@eecs.berkeley.edu.
The position measurements are noisy and occur with detection probability less than one, and there is a noise background of spurious position reports, i.e., false alarms or clutter.

The essence of the multi-target tracking problem is to find tracks from the noisy measurements. Now, if the sequence of measurements associated with each target is known, multi-target tracking (at least under the assumption of independent motion) reduces to a set of state estimation problems, which, for the purposes of this paper, we assume to be straightforward. Unfortunately, the association between measurements and targets is unknown. The data association problem is to work out which measurements were generated by which targets; more precisely, we require a partition of measurements such that each element of a partition is a collection of measurements generated by a single target or clutter [6]. In the general case, uncertainty as to the correct association is unavoidable.

Multi-target tracking algorithms are often categorized according to the objective function that they purport to optimize:

- **Heuristic** approaches typically involve no explicit objective function. For example, the greedy nearest-neighbor filter (NNF) [1] processes the new measurements in some order and associates each with the target whose predicted position is closest, thereby selecting a single association after each scan. Although effective under benign conditions, the NNF gives order-dependent results and breaks down under more difficult circumstances.

- **Bayesian** approaches: (1) *Maximum a posteriori* (MAP) approaches find the most probable association, given the measurements made so far, and estimate tracks given this association. (2) Bayes estimator approaches estimate tracks by minimizing the posterior expected value of some risk function. When the mean squared error is used as a risk function, the Bayes estimator is an *minimum mean-square error* (MMSE) estimate. The MMSE estimates of tracks are computed by summing over all possible associations, weighted by their posteriors.

Tracking algorithms can also be categorized by the way in which they process measurements:

- **Single-scan** algorithms estimate the current states of targets based on their previously estimated states and the current scan of measurements. Like recursive state estimation methods (e.g., the Kalman filter), such methods can compute exact posteriors because the previous estimate is a sufficient statistic, but unfortunately the complexity of the exact posterior grows exponentially with time. Single-scan algorithms typically use a highly simplified approximate representation of the posterior state estimate.

- **Multi-scan** algorithms estimate the current states of targets based on their previously estimated
states, multiple past scans and the current scan of measurements. They may revisit past scans when processing each new scan, and can thereby revise previous estimates in the light of new evidence.

MAP approaches include the well-known *multiple hypothesis tracking* (MHT) algorithm [7]. MHT is a multi-scan tracking algorithm that maintains multiple hypotheses associating past measurements with targets. When a new set of measurements arrives, a new set of hypotheses is formed from each previous hypothesis. The algorithm returns a hypothesis with the highest posterior as a solution. MHT is categorized as a “deferred logic” method [8] in which the decision about forming a new track or removing an existing track is delayed until enough measurements are collected. MHT is capable of initiating and terminating a varying number of tracks and is suitable for autonomous surveillance applications. The main disadvantage of MHT in its pure form is its computational complexity since the number of hypotheses grows exponentially over time. Various heuristic methods have been developed to control this growth [7,9,10]; but these methods sacrifice the MAP property. Other MAP approaches have been tried besides MHT, including 0-1 integer programming [11] and multidimensional assignment [8]. As the latter reference shows, the underlying MAP data association problem is NP-hard, so we do not expect to find efficient, exact algorithms.

Bayes estimator approaches to solve data association problems are even less tractable than the MAP computation. Several “pseudo-Bayesian” methods have been proposed, of which the best-known is the *joint probabilistic data association* (JPDA) filter [1]. JPDA is a suboptimal single-scan approximation to the optimal Bayesian filter; it can also be viewed as an *assumed-density* filter in which the joint posterior distribution is approximated by a product of simpler distributions such as moment-matching Gaussian distributions. At each time step, instead of finding a single best association between measurements and tracks, JPDA enumerates all possible associations and computes association probabilities \( \{ \beta_{jk} \} \), where \( \beta_{jk} \) is the probability that the \( j \)th measurement extends the \( k \)th track. Given an association, the state of a target is estimated by a filtering algorithm and this conditional state estimate is weighted by the association probability. Then the state of a target is estimated by summing over the weighted conditional estimates. JPDA has proved very effective in cluttered environments compared with NNF [1]. The exact calculation of association probabilities \( \{ \beta_{jk} \} \) in JPDA, which requires the summation over all association event probabilities, is NP-hard [12] since the related problem of finding the permanent of a matrix is \#P-complete [13,14]. Some heuristic approaches to approximate JPDA include a “cheap” JPDA algorithm

---

1 A \#P-complete problem is computationally equivalent to computing the number of accepting computations of a polynomial-time nondeterministic Turing machine and \#P contains NP [13].
“suboptimal” JPDA \cite{16} and “near-optimal” JPDA \cite{17}. In \cite{18}, a single-scan data association problem is considered and a leave-one-out heuristic is developed to avoid the enumeration of all possible associations. Other Bayes estimator approaches include the probability hypothesis density (PHD) filter \cite{19,20}, probabilistic multi-hypothesis tracking (PMHT) \cite{21}, and mixture reduction \cite{22}, to name a few.

The main contribution of this paper is the development of a real-time multi-target tracking method called Markov chain Monte Carlo data association (MCMCDA). Unlike MHT and JPDA, MCMCDA is a true approximation scheme for the optimal Bayesian filter; i.e., when run with unlimited resources, it converges to the Bayesian solution. As the name suggests, MCMCDA uses Markov chain Monte Carlo (MCMC) sampling instead of enumerating over all possible associations. MCMC was first used to solve data association problems by Pasula et al. \cite{23,24}, who showed it to be effective for multi-camera traffic surveillance problems involving hundreds of vehicles. More recently, in \cite{25}, MCMC was used to approximate the association probabilities in JPDA and was shown to outperform Fitzgerald’s cheap JPDA. \footnote{MCMC has also been used for problems that are roughly isomorphic to the data association problem, including state estimation in the switching Kalman filter \cite{26} and stereo correspondence in computer vision \cite{3}.}

MCMCDA goes beyond these contributions by incorporating missing measurements, false alarms and an ability to initiate and terminate tracks, so that the algorithm can be applied to the full range of data association problems.

The paper has two main technical results. The first is a theorem showing that, when the number of targets is fixed, single-scan MCMCDA is a fully polynomial randomized approximation scheme for JPDA. More specifically, for any \( \epsilon > 0 \) and any \( 0 < \eta < 0.5 \), the algorithm finds estimates within ratio \( \epsilon \) with probability at least \( 1 - \eta \) in time complexity \( O(\epsilon^{-2} \log \eta^{-1} N (N \log N + \log(\epsilon^{-1}))) \), where \( N \) is the number of measurements. The theorem is based on the seminal work of Jerrum and Sinclair \cite{13}, who designed an MCMC algorithm for approximating the permanent of a matrix and developed new techniques for analyzing its rate of convergence. As mentioned earlier, the relationship between JPDA and computing the permanent was identified by Collins and Uhlmann \cite{12}; the connection to the polynomial-time approximation theorems of Jerrum and Sinclair was first noticed by Pasula et al. \cite{23}. Although our proof has the same structure as that of Jerrum and Sinclair, substantial technical work was required to complete the mapping from computing the permanent to solving JPDA, including the usage of gating conditions that ensure appropriate lower bounds on individual association probabilities. In addition, we present simulation results supporting our theoretical results.

Our second technical result is the complete specification of the transition structure for a multi-scan...
version of MCMCDA that includes detection failure, false alarms, and track initiation and termination. We prove that the resulting algorithm converges to the full Bayesian solution and present simulation results supporting the convergence result. We also provide the first extensive experimental investigation of MCMCDA’s performance on classical data association problems. We demonstrate remarkably effective real-time performance of MCMCDA compared to MHT under extreme conditions, such as a large number of targets in a dense environment, low detection probabilities, and high false alarm rates. We also present an example in which MCMCDA runs 20 times faster than MHT while outperforming MHT.

The remainder of this paper is structured as follows. The multi-target tracking problem and its probability model are described in Section II. In Section III, the Markov chain Monte Carlo (MCMC) method is summarized. The single-scan MCMCDA algorithm is presented in Section IV along with the proof that it approximates JPDA in polynomial time. The multi-scan MCMCDA algorithm is described in Section V.

II. Multi-Target Tracking

A. Problem Formulation

Let $T \in \mathbb{Z}^+$ be the duration of surveillance. Let $K$ be the (unknown) number of objects that appear in the surveillance region $\mathcal{R}$ during the surveillance period. Each object $k$ moves in $\mathcal{R}$ for some unknown duration $[t^k_{i}, t^k_{f}] \subseteq [1, T]$. Each object arises at a random position in $\mathcal{R}$ at $t^k_{i}$, moves independently around $\mathcal{R}$ until $t^k_{f}$ and disappears. At each time, an existing target persists with probability $1 - p_z$ and disappears with probability $p_z$. The number of objects arising at each time over $\mathcal{R}$ has a Poisson distribution with parameter $\lambda_b V$ where $\lambda_b$ is the birth rate of new objects per unit time, per unit volume, and $V$ is the volume of $\mathcal{R}$. The initial position of a new object is uniformly distributed over $\mathcal{R}$.

Let $F^k : \mathbb{R}^{n_x} \rightarrow \mathbb{R}^{n_x}$ be the discrete-time dynamics of the object $k$, where $n_x$ is the dimension of the state variable, and let $x^k_t \in \mathbb{R}^{n_x}$ be the state of the object $k$ at time $t$. The object $k$ moves according to

$$x^k_{t+1} = F^k(x^k_t) + w^k_t, \quad \text{for } t = t^k_{i}, \ldots, t^k_{f} - 1,$$

where $w^k_t \in \mathbb{R}^{n_x}$ are white noise processes.

The noisy observation (or measurement) of the state of the object is measured with a detection probability $p_d$. With probability $1 - p_d$, the object is not detected and we call this a missing observation. There are also false alarms and the number of false alarms has a Poisson distribution with a parameter

\[^3\] We assume that targets are indistinguishable in this paper, but if observations include target type or attribute information, the state variable can be extended to include target type information.

\[^4\] The terms observation and measurement are used interchangeably in this paper.
\( \lambda_t V \) where \( \lambda_t \) is the false alarm rate per unit time, per unit volume. Let \( n_t \) be the number of observations at time \( t \), including both noisy observations and false alarms. Let \( y_t^j \in \mathbb{R}^{n_y} \) be the \( j \)th observation at time \( t \) for \( j = 1, \ldots, n_t \), where \( n_y \) is the dimension of each observation vector. Each object generates an observation at each sampling time if it is detected. Let \( H^j : \mathbb{R}^{n_x} \rightarrow \mathbb{R}^{n_y} \) be the observation model. Then the observations are generated as follows:

\[
y_t^j = \begin{cases} 
H^j(x_k^t) + v_t^j & \text{if the } j \text{th observation is from } x_k^t \\
u_t & \text{otherwise,}
\end{cases}
\] (2)

where \( v_t^j \in \mathbb{R}^{n_y} \) are white noise processes and \( u_t \sim \text{Unif}(\mathbb{R}) \) is a random process for false alarms.

The multi-target tracking problem is to estimate \( K \), \( \{t^k_i, t^k_f\} \) and \( \{x_k^t : t^k_i \leq t \leq t^k_f\} \), for \( k = 1, \ldots, K \), from observations.

**B. Probability Model**

In order to perform Bayesian inference on a multi-target tracking problem, we need first to specify the probability model for multi-target tracking. This section describes the probability model and derives a formula for computing the posterior (up to a normalizing constant).

Suppose that \( \omega \) denotes a set of parameters of interest. \( \omega \) is not directly observable. Instead, we make a set of measurements \( Y \). The objective of Bayesian inference is to make probability statements about \( \omega \) given \( Y \). For this objective, we first need a joint probability distribution \( P(\omega, Y) \). Then the posterior \( P(\omega|Y) \) can be represented as below using Bayes rule:

\[
P(\omega|Y) = \frac{P(\omega, Y)}{\int P(\omega, Y) d\omega} = \frac{P(Y|\omega)P(\omega)}{P(Y)},
\] (3)

where \( P(\omega) \) is the prior distribution of \( \omega \) and \( P(Y|\omega) \) is the likelihood of \( Y \) given \( \omega \).

In the probability model for multi-target tracking, \( \omega \) is an association event, i.e., a partition of measurements such that each element of the partition is a collection of measurements generated by a single target or clutter \([6]\). Since, in general, there is no closed-form formula for computing \( P(Y) \), one can only compute \( P(\omega|Y) \) up to a normalizing constant, which requires computation of \( P(Y|\omega) \) and \( P(\omega) \). For a fixed association event \( \omega \), \( P(Y|\omega) \) can be computed by solving a set of single-target tracking problems. Hence, we focus our attention to the derivation of \( P(\omega) \) in the remainder of this section.

We first define \( \{\omega\} \) for all possible measurement sizes. Let \( \mu \) be a nonnegative \( T \)-dimensional vector, i.e., \( \mu = [\mu_1, \ldots, \mu_T]^T \), representing the possible numbers of measurements from \( t = 1 \) to \( t = T \), where \( \mu_t \in \mathbb{Z}^+ \cup \{0\} \). For each value of \( \mu \), define a set of measurement indices \( \Upsilon_t^\mu = \{(t, 1), (t, 2), \ldots, (t, \mu_t)\} \) for \( \mu_t > 0 \), where \( (t, i) \) is an index to the \( i \)th measurement at time \( t \), and \( \Upsilon_t^\mu = \emptyset \) for \( \mu_t = 0 \). Now
let $\Upsilon^\mu = \bigcup_{t=1}^T \Upsilon_t^\mu$ be an index set to a set of measurements whose size matches $\mu$ and let the set 
\{\Upsilon^\mu : \mu \in \mathbb{Z}^T\} contain all possible index sets.

For each $\mu$, let $\Omega^\mu$ be a collection of partitions of $\Upsilon^\mu$ such that, for $\omega \in \Omega^\mu$, $\omega = \{\tau_0, \tau_1, \ldots, \tau_K\}$, where $\tau_0$ is a set of indices to false alarms and $\tau_k$ is a set of indices to measurements from target $k$, for $k = 1, \ldots, K$. More formally, $\omega \in \Omega^\mu$ is defined as follows:

1) $\omega = \{\tau_0, \tau_1, \ldots, \tau_K\}$;
2) $\bigcup_{k=0}^K \tau_k = \Upsilon^\mu$ and $\tau_i \cap \tau_j = \emptyset$ for $i \neq j$;
3) $\tau_0$ is a set of indices to false alarms; and
4) $|\tau_k \cap \Upsilon_t^\mu| \leq 1$ for $k = 1, \ldots, K$ and $t = 1, \ldots, T$;

Here, $K = K(\omega)$ is the number of tracks for the given partition $\omega \in \Omega^\mu$ and $|S|$ denotes the cardinality of the set $S$. We call $\tau_k$ a track when there is no confusion, although the actual track is a sequence of state estimates computed from the observations indexed by $\tau_k$. (We assume there is a deterministic function that returns a sequence of estimated states given a set of observations, so no distinction is required.) The fourth requirement says that a track can have at most one observation at each time, but, in the case of multiple sensors with overlapping sensing regions, we can easily relax this requirement to allow multiple observations per track. For special cases in which $p_d = 1$ or $\lambda_t = 0$, the definition of $\Omega^\mu$ can be adjusted accordingly.

**Example 1:** Let $T = 5$ and $\mu = [2, 2, 2, 2, 2]^T$; then
\[
\Upsilon^\mu = \{(1, 1), (1, 2), (2, 1), (2, 2), (3, 1), (3, 2), (4, 1), (4, 2), (5, 1), (5, 2)\}.
\]

An example of $\omega \in \Omega^\mu$ is $\omega = \{\tau_0, \tau_1, \tau_2\}$, where $\tau_0 = \{(3, 2)\}$, $\tau_1 = \{(1, 1), (2, 1), (3, 1), (4, 1), (5, 1)\}$, and $\tau_2 = \{(1, 2), (2, 2), (4, 2), (5, 2)\}$. This example is shown in Figure 1.

Now let $\tilde{\Omega} = \{\omega \in \Omega^\mu : \mu \in \mathbb{Z}^T\}$. Notice that $\mu = \mu(\omega)$ is a deterministic function of $\omega \in \tilde{\Omega}$. In addition, we can compute the following numbers from $\omega \in \tilde{\Omega}$:

- $e_t$, the number of targets present at time $t$ with $e_0 = 0$;
- $z_t$, the number of targets terminated at time $t$ with $z_1 = 0$;
- $a_t$, the number of new targets at time $t$;
- $d_t$, the number of detected targets at time $t$; and
- $f_t$, the number of false alarms at time $t$, $f_t = \mu_t - d_t$.

Since these numbers are deterministic functions of $\omega \in \tilde{\Omega}$, we have $P(\omega) = P(\omega, \mathcal{N}) = P(\omega|\mathcal{N})P(\mathcal{N})$, where $\mathcal{N} = \{\mu_t, e_t, z_t, a_t, d_t : 1 \leq t \leq T\}$. Based on the target termination, target detection, new target
arrival, and false alarm models described in Section II-A, we have
\[
P(N) = \prod_{t=1}^{T} \left[ \frac{e_{t-1}}{z_t} \right] p_{\omega}^z(1 - p_z)^{e_{t-1} - z_t} \left( \frac{e_{t-1} - z_t + a_t}{d_t} \right) p_d^{d_t}(1 - p_d)^{e_{t-1} - z_t + a_t - d_t} \times \frac{(\lambda_b V)^{a_t}}{a_t!} \exp(-\lambda_b V) \frac{(\lambda_V f_t)^{d_t}}{d_t!} \exp(-\lambda_V). \tag{4}
\]

Since \( \omega \in \tilde{\Omega} \) with the same \( N \) are indistinguishable, i.e., invariant under permutation of target indices, they are exchangeable and we assign a uniform prior on them. Hence,
\[
P(\omega|N) \propto \prod_{t=1}^{T} \left[ \frac{e_{t-1}}{z_t} \right] \left( \frac{e_{t-1} - z_t + a_t}{d_t} \right) \left( \frac{\mu_t}{d_t} \right) \left( \frac{d_t}{a_t} \right)! (d_t - a_t)! \tag{5}
\]

Combining (4) and (5), the prior \( P(\omega) \) is
\[
P(\omega) \propto \prod_{t=1}^{T} \frac{1}{\mu_t!} p_{\omega}^z(1 - p_z)^{e_{t-1} - z_t} p_d^{d_t}(1 - p_d)^{e_{t-1} - z_t + a_t - d_t} (\lambda_b V)^{a_t} (\lambda_V)^{\mu_t - d_t}. \tag{6}
\]

We simplify (6) by letting \( c_t = e_{t-1} - z_t \) be the number of targets from time \( t-1 \) that have not terminated at time \( t \), and \( g_t = e_{t-1} - z_t + a_t - d_t \) be the number of undetected targets. Then, the prior model (6) becomes
\[
P(\omega) \propto \prod_{t=1}^{T} \frac{1}{\mu_t!} p_{\omega}^z(1 - p_z)^{c_t} p_d^{d_t}(1 - p_d)^{g_t} (\lambda_b V)^{\mu_t} (\lambda_V)^{f_t}. \tag{7}
\]

Let \( Y_t = \{ y^j_t : j = 1, \ldots, n_t \} \) be all measurements at time \( t \) and \( Y = \{ Y_t : 1 \leq t \leq T \} \) be all measurements from \( t = 1 \) to \( t = T \). \( Y_t \) can be considered as a vector with random ordering as indicated by the exchangeability of indices in (5). Applying Bayes rule, the posterior of \( \omega \in \tilde{\Omega} \) becomes:
\[
P(\omega|Y) \propto P(Y|\omega) P(\omega) \tag{8}
\]

with \( P(\omega) \) given in (7).

It is important to notice that \( P(Y|\omega) = 0 \) if \( \mu(\omega) \neq n(Y) \), where \( n(Y) = [n_1(Y), \ldots, n_T(Y)]^T \) denotes the number of measurements at each time in \( Y \). Hence, we can restrict our attention to those \( \omega \in \tilde{\Omega} \) with \( \mu(\omega) = n(Y) \). This crucial observation makes the numerous computations based on (8) practical. The set of all possible associations is now defined as \( \Omega := \Omega^n(Y) = \{ \omega \in \tilde{\Omega} : \mu(\omega) = n(Y) \} \) and \( \Omega \) is used instead of \( \tilde{\Omega} \) throughout this paper. Thus, it is convenient to view \( \Omega \) as a collection of partitions of \( Y \). An example of one such partition is shown in Figure 1.

The posterior (8) can be further simplified as
\[
P(\omega|Y) \propto P(Y|\omega) \prod_{t=1}^{T} p_{\omega}^z(1 - p_z)^{c_t} p_d^{d_t}(1 - p_d)^{g_t} (\lambda_b V)^{\mu_t} (\lambda_V)^{f_t}, \tag{9}
\]
where the term $\prod_{t=1}^{T} V_{a_t} f_t$ will be canceled out by the matching initial state and false alarm densities in $P(Y|\omega)$. The likelihood $P(Y|\omega)$ can be computed based on the chosen dynamic and measurement models. For example, the computation of $P(Y|\omega)$ for linear dynamic and measurement models can be found in [27].

The posterior $P(\omega|Y)$ can be applied to both MAP and Bayes estimator approaches to solve the multi-target tracking problem. In the MAP approach, we first seek $\hat{\omega}$ such that

$$\hat{\omega} = \arg \max_{\omega \in \Omega} P(\omega|Y).$$  \hspace{1cm} (10)$$

Then the states of the targets are estimated based on $\hat{\omega}$. 

In the Bayes estimator approach, we look for Bayesian estimates of parameters. For instance, if we are interested in estimating the state $x_{kt}$ of target with the label $k$, the MMSE estimate of $x_{kt}$ is:

$$\hat{x}_{kt} = \sum_{\omega \ni \tau_k} \int x_{kt} P(dx_{kt}|\omega, Y) P(\omega|Y).$$  \hspace{1cm} (11)$$

Notice that it considers the contribution of all $\omega$ that contain a target with the label $k$ when computing $\hat{x}_{kt}$, whereas the MAP approach uses only $\hat{\omega}$. The method proposed in this paper (Algorithm 3) can be used to find both MAP and Bayes estimators to the multi-target tracking problem.

### III. Markov Chain Monte Carlo

Markov chain Monte Carlo (MCMC) plays a significant role in many fields such as physics, statistics, economics, finance, and engineering [28, 29, 30]. The MCMC method includes algorithms such as Gibbs sampling [31] and the Metropolis-Hastings algorithm [32, 33]. Beichl and Sullivan described the Metropolis-Hastings algorithm as “the most successful and influential of all the members of ... the Monte Carlo Method” [29]. MCMC techniques have been applied to complex probability distribution integration
MCMCDA problems, counting problems, and combinatorial optimization problems\textsuperscript{29}. In some cases, MCMC is the only known general algorithm that finds a good approximate solution to a complex problem in polynomial time\textsuperscript{13}.

MCMC is a general method to generate samples from a distribution $\pi$ on a space $\Omega$ by constructing a Markov chain $\mathcal{M}$ with states $\omega \in \Omega$ and stationary distribution $\pi(\omega)$. We now describe an MCMC algorithm known as the Metropolis-Hastings algorithm. If $\mathcal{M}$ is at state $\omega \in \Omega$, $\omega' \in \Omega$ is proposed following the proposal distribution $q(\omega, \omega')$. The move is accepted with an acceptance probability $A(\omega, \omega')$ where

$$A(\omega, \omega') = \min\left(1, \frac{\pi(\omega')q(\omega', \omega)}{\pi(\omega)q(\omega, \omega')}\right),$$

otherwise the sampler stays at $\omega$. With this construction, the detailed balance condition is satisfied, i.e., for all $\omega, \omega' \in \Omega$,

$$Q(\omega, \omega') := \pi(\omega)P(\omega, \omega') = \pi(\omega')P(\omega', \omega),$$

where $P(\omega, \omega') = q(\omega, \omega')A(\omega, \omega')$ is the transition probability from $\omega$ to $\omega'$. Hence, $\mathcal{M}$ is a reversible Markov chain.\textsuperscript{5}

If $\mathcal{M}$ is also irreducible and aperiodic,\textsuperscript{6} then $\mathcal{M}$ converges to its stationary distribution by the ergodic theorem\textsuperscript{34}. Hence, for any bounded function $f$, the sample mean $\bar{f} = \frac{1}{N} \sum_{n=1}^{N} f(\omega^{(n)})$ converges to $\mathbb{E}_\pi f(\omega)$ as $N \to \infty$, where $\omega^{(n)}$ is the state of $\mathcal{M}$ at the $n$th MCMC step and $\mathbb{E}_\pi f(\omega)$ is the expected value of $f(\omega)$ with respect to measure $\pi$. Notice that (12) requires only the ability to compute the ratio $\pi(\omega')/\pi(\omega)$, avoiding the need to normalize $\pi$, and this is why MCMC, especially the Metropolis-Hastings algorithm, can be applied to a wide range of applications.

An ergodic chain $\mathcal{M}$ on state space $\Omega$ converges to its stationary distribution asymptotically. But a practical question is how fast $\mathcal{M}$ approaches stationarity. One way to measure the rate of convergence of $\mathcal{M}$ to stationarity is the “mixing time” of the Markov chain. Let $P$ be the transition probabilities of $\mathcal{M}$ and let $P^{(n)}(\cdot)$ be the distribution of the state at the $n$th MCMC step given that $\mathcal{M}$ is started from the initial state $\omega \in \Omega$. If $\pi$ is the stationary distribution of $\mathcal{M}$, then the total variation distance at the

\textsuperscript{5} A Markov chain is reversible with respect to $\pi$ if it is positively recurrent and the detailed balance condition (13) is satisfied.

\textsuperscript{6} A Markov chain is irreducible when every state is accessible from every other state. A Markov chain is periodic if there exists at least one state to which the Markov chain returns with a fixed time period greater than one. A Markov chain is aperiodic if no such state exists.
The $n^{th}$ MCMC step with initial state $\omega$ is defined as
\[
\Delta_\omega(n) = \|P^{(n)}_\omega - \pi\|_V = \max_{S \subset \Omega} |P^{(n)}_\omega(S) - \pi(S)| = \frac{1}{2} \sum_{y \in \Omega} |P^{(n)}_\omega(y) - \pi(y)|.
\]  

(14)

The rate of convergence of $M$ to stationarity can be measured by the mixing time
\[
\tau_\omega(\epsilon) = \min\{n : \Delta_\omega(s) \leq \epsilon \text{ for all } s \geq n\}.
\]

(15)

After the mixing time $\tau_\omega(\epsilon)$, $P^{(n)}_\omega(\cdot)$ for $n \geq \tau_\omega(\epsilon)$ is very close to the stationary distribution $\pi$.

One approach to bound $\tau_\omega(\epsilon)$ of a Markov chain with a complex structure is the canonical path method [13]. In this paper, the canonical path method is used to bound $\tau_\omega(\epsilon)$ of the Markov chain simulated by the MCMCDA algorithm given in Section IV. For the remainder of this section, we describe the canonical path method.

For a finite, reversible and ergodic Markov chain $M$ with state space $\Omega$, consider an undirected graph $G = (V, E)$ where $V = \Omega$ and $E = \{(x, y) : Q(x, y) > 0\}$ (recall the definition of $Q(\cdot, \cdot)$ from (13)). So an edge $(x, y) \in E$ indicates that the Markov chain $M$ can make a transition from $x$ to $y$ or from $y$ to $x$ in a single step. For each ordered pair $(x, y) \in \Omega^2$, the canonical path $\gamma_{xy}$ is defined as a simple path from $x$ to $y$ in $G$. In terms of $M$, the canonical path $\gamma_{xy}$ is a sequence of legal transitions from $x$ to $y$ in $\mathcal{M}$. Let $\Gamma = \{\gamma_{xy} : x, y \in \Omega\}$ be the set of all canonical paths. Now the mixing time of the chain is related to the maximum edge loading:
\[
\bar{\rho} = \bar{\rho}(\Gamma) = \max_e \frac{1}{Q(e)} \sum_{\gamma_{xy} \ni e} \pi(x)\pi(y)|\gamma_{xy}|,
\]

(16)

where $|\gamma_{xy}|$ denotes the length of the path $\gamma_{xy}$. If $\bar{\rho}$ is not so big, i.e., no single edge is overloaded, then the Markov chain can mix rapidly. The main result for the canonical path method is as follows [13][35]:

**Theorem 1:** Let $M$ be a finite, reversible, ergodic Markov chain with loop probabilities $P(x, x) \geq \frac{1}{2}$ for all states $x$. Let $\Gamma$ be a set of canonical paths with maximum edge loading $\bar{\rho}$. Then the mixing time of $M$ satisfies $\tau_\omega(\epsilon) \leq \bar{\rho}(\log \pi(x)^{-1} + \log \epsilon^{-1})$, for any choice of initial state $\omega$.

IV. SINGLE-SCAN MCMCDA

In this section, we consider a special case of the multi-target tracking problem described in Section II in which the number of targets $K$ is known. We begin by specifying the optimal single-scan Bayesian filter, noting that it is infeasible to implement the optimal filter in practice due to its computational complexity. We then define the **assumed-density** single-scan Bayesian filter, which is frequently used in

\footnote{A simple path in a graph is a path with no repeated vertices.}
practice as an approximation to the optimal filter. The well-known JPDA filter [1] is an example of this approach. Although JPDA is less computationally demanding than the optimal single-scan Bayesian filter, the data association aspect remains intractable. We show, nevertheless, that the single-scan MCMCDA algorithm finds an $\epsilon$-good approximate solution to JPDA in polynomial time.

A. Optimal Single-Scan Bayesian Filter

The (optimal) single-scan Bayesian filter for multi-target tracking is a recursive filtering algorithm in which each measurement is processed in turn and the posterior distribution of the current state is computed based on the current measurements and the posterior distribution computed at the previous scan. It resembles an ordinary recursive filter (e.g., a Kalman filter) for single-target tracking, but there are two major differences: first, the filter must compute the joint posterior of all target states, whose complexity grows without bound over time; second, the likelihood model for observations factors conditional on the (unknown) association variable, and so the exact update step must sum over exponentially many possible associations.

Let $X_t = (X_t^1, \ldots, X_t^K)$ be the joint state of all targets at time $t$. We assume the availability of the prior distribution $P(X_0)$. Now suppose that we are at time $t$ and the optimal single-scan Bayesian filter has computed the posterior distribution $P(X_{t-1}|y_{1:t-1})$ from the previous scan time $t-1$, where $y_{1:t-1} = \{y_1, \ldots, y_{t-1}\}$ is a set of all past measurements. The optimal single-scan Bayesian filter computes $P(X_t|y_{1:t})$ from the new measurements $y_t$ and the previous posterior distribution $P(X_{t-1}|y_{1:t-1})$ using the prediction and measurement update steps. For a graphical illustration, see Figure 2.
Step 1 (Prediction): Using $P(x_{t-1}|y_{1:t-1})$, compute the distribution

$$P(X_t|y_{1:t-1}) = \int P(X_t|x_{t-1}, y_{1:t-1})P(x_{t-1}|y_{1:t-1})dx_{t-1}$$

$$= \int P(X_t|x_{t-1})P(x_{t-1}|y_{1:t-1})dx_{t-1}, \quad (17)$$

where the Markovian assumption is used in the second equality and $P(X_t|x_{t-1})$ is determined by the dynamics model (1).

Step 2 (Measurement Update): In general, Bayes rule can be applied to compute the desired posterior

$$P(X_t|y_{1:t}) = \frac{P(y_t|X_t, y_{1:t-1})P(X_t|y_{1:t-1})}{\int P(y_t|x_t, y_{1:t-1})P(x_t|y_{1:t-1})dx_t}. \quad (18)$$

But, since we do not know which measurement is originated from which target, we cannot compute $P(y_t|X_t, y_{1:t-1})$ directly. Instead, we introduce a latent variable $\omega_t$ to represent a possible association between $n_t$ measurements and $K$ targets and we let $\Omega_t = \{\omega_t\}$ be a set of all possible association events at time $t$. The formal definition of $\Omega_t$ resembles the definition in Section II-B and is given in Section IV-B.

Using the total probability theorem, we can compute

$$P(X_t|y_{1:t}) = \sum_{\omega_t \in \Omega_t} P(X_t|\omega_t, y_{1:t})P(\omega_t|y_{1:t}), \quad (19)$$

where

$$P(X_t|\omega_t, y_{1:t}) = \frac{P(y_t|X_t, \omega_t, y_{1:t-1})P(X_t|y_{1:t-1})}{\int P(y_t|x_t, \omega_t, y_{1:t-1})P(x_t|y_{1:t-1})dx_t}.$$  

Because $\omega_t$ specifies the association between measurements and targets, the term $P(y_t|X_t, \omega_t, y_{1:t-1})$ in (19) can be computed easily—according to the standard observation model, it simplifies to a product of independent likelihood factors, one per target/observation pair. Thus, we can compute $P(X_t|y_{1:t})$ in (19); unfortunately, the summation over $\omega_t$ has exponentially many terms. Not only is this summation intractable, but as a consequence the posterior representation becomes exponentially more complex at each time step.

B. Assumed-Density Single-Scan Bayesian Filter

Complexity in filtering problems is often addressed by a generic approach often called assumed-density filtering [36], in which the posterior state distribution is assumed to belong to a fixed family of density functions. Each exact update step typically takes the posterior outside this family, but a projection step then finds the best approximation within the family. Thus, an assumed-density single-scan Bayesian filter for multi-target tracking uses a simplified approximate representation for the posterior over the joint
state of the targets. For example, one can make an (incorrect) independence assumption about the joint posterior, approximating it by a product of marginal distributions:

\[
P(X_t | y_{1:t}) = P(X_t^1, \ldots, X_t^K | y_{1:t}) \approx \prod_{k=1}^{K} P(X_t^k | y_{1:t}). \tag{20}
\]

This assumption is made by the JPDA filter, which has been traditionally used with the Kalman filter, assuming linear–Gaussian models, i.e., linear dynamic and measurement models and white Gaussian noise processes \([1]\). In fact, the assumed-density method with a factored posterior can be used with the general dynamics and measurement models defined in Section II. Furthermore, whereas JPDA sums over the association hypotheses in \((19)\), the single-scan MCMCDA filter described in Section IV-C approximates this sum efficiently using MCMC.

The independence assumption made in \((20)\) makes it possible to apply a standard recursive filtering update to each target separately, but only if conditioned on the (unknown) association between targets and observations. Thus, the measurement update step has to consider possible associations. This update step has two phases: first, measurement validation (another approximation) identifies the mappings between observations and targets that are considered plausible under some threshold; then state update computes the new approximate posterior distribution.

We begin with an (approximate) posterior distribution \(\hat{P}(X_{t-1}^k | y_{1:t-1})\) computed from the previous time \(t - 1\), for each target \(k\), where \(\hat{P}(X_t^k | y_{1:t})\) approximates \(P(X_t^k | y_{1:t})\) according to the independence assumption and the measurement validation step described below. At time \(t\), the following three steps show how the assumed-density single-scan Bayesian filter computes \(\hat{P}(X_t^k | y_{1:t})\) from the new measurements \(y_t\) and the previous posterior distribution \(\hat{P}(X_{t-1}^k | y_{1:t-1})\).

**Step 1 (Prediction):** Similar to the prediction step \((17)\) of the optimal single-scan Bayesian filter, for each \(k\), we compute

\[
\hat{P}(X_t^k | y_{1:t-1}) := \int P(X_t^k | x_{t-1}^k, y_{1:t-1}) \hat{P}(x_{t-1}^k | y_{1:t-1}) dx_{t-1}^k = \int P(X_t^k | x_{t-1}^k) \hat{P}(x_{t-1}^k | y_{1:t-1}) dx_{t-1}^k. \tag{21}
\]

**Step 2 (Measurement Validation):** Since there can be a large number of measurements and some measurements are very unlikely to have originated from a particular target, the state of each target is

\[8\] Recently, JPDA has also been applied to nonlinear problems using a particle filter \([37]\). Notice that when the dynamics and measurement model are nonlinear or the noise processes are non-Gaussian, the posterior distribution can be approximated using techniques such as linearization, unscented filtering \([38]\), interacting multiple models \([39]\), particle filters \([40]\), or other numerical methods.
Fig. 3. (a) An example of measurement validation. For this 2D example, $\hat{P}^k(y|y_{1:t-1})$ is a Gaussian density with mean $\hat{y}^k$ for $k = 1, 2, 3$ (shown as a solid triangle). Measurements $\{y^j : j = 1, 2, \ldots, 8\}$ are shown as disks. A measurement is validated for target $k$ if it is inside the shaded region centered at $\hat{y}^k$. (b) Measurement validation encoded as a bipartite graph $G = (U, V, E)$. An edge between $y^j \in U$ and $k \in V$ indicates that measurement $y^j$ is validated for target $k$ and $(y^j, k) \in E$. (The subscript $t$ is omitted.)

estimated from a subset of measurements. The process of selecting a subset of measurements for state estimation is called measurement validation. Let $\hat{P}^k(Y^j_t|y_{1:t-1})$ be the probability density of having observation $Y^j_t$ given $y_{1:t-1}$, when $Y^j_t$ is a measurement originated from target $k$. For each $k$ and $j$, compute the distribution

$$
\hat{P}^k(Y^j_t|y_{1:t-1}) := \int P(Y^j_t|x^k_t, y_{1:t-1}) \hat{P}(x^k_t|y_{1:t-1}) dx^k_t
$$

$$
= \int P(Y^j_t|x^k_t) \hat{P}(x^k_t|y_{1:t-1}) dx^k_t,
$$

(22)

where the second equality uses the fact the current observation is independent of previous observations given the current state and $P(Y^j_t|x^k_t)$ is determined by the measurement model (2). For linear–Gaussian models, $\hat{P}^k(Y^j_t|y_{1:t-1})$ is a Gaussian distribution and completely determined by its mean and variance. The measurement $y^j_t$ is validated for target $k$ if and only if

$$
\hat{P}^k(y^j_t|y_{1:t-1}) \geq \delta^k,
$$

(23)

where $\delta^k$ are appropriate thresholds. An example of measurement validation is shown in Figure 3(a).

Step 3 (State Estimation): As in the measurement update step in the optimal single-scan Bayesian filter, we introduce a latent variable $\omega$ to represent a feasible association between $n_t$ measurements and $K$ targets and we let $\Omega_t = \{\omega\}$ be a set of all feasible (joint) association events at time $t$. For each $\omega \in \Omega_t$, $\omega = \{(j, k)\}$, where $(j, k)$ denotes the event that observation $j$ is associated with target $k$. An
association event $\omega$ is feasible when (i) for each $(j, k) \in \omega$, $y^j_t$ is validated for target $k$; (ii) an observation is associated with at most one target; and (iii) a target is associated with at most one observation.

Let $N \leq n_t$ be the number of validated observations. We encode the feasible association events in a bipartite graph $G = (U, V, E)$, where $U = \{y^j_t : 1 \leq j \leq N\}$ is a vertex set of validated observations, $V = \{k : 1 \leq k \leq K\}$ is a vertex set of target indices, and $E = \{(u, v) : u \in U, v \in V, \hat{P}^{uv}(u|y_1:t-1) \geq \delta^v\}$. An edge $(u, v) \in E$ indicates that observation $u$ is validated for target $v$ according to (23). An example of measurement validation encoded as a bipartite graph is shown in Figure 3(b). A feasible association event is a matching in $G$, i.e., a subset $M \subset E$ such that no two edges in $M$ share a vertex. The set of all feasible association events $\Omega_t$ can be represented as $\Omega_t = \Omega_0(G) \cup \cdots \cup \Omega_K(G)$, where $\Omega_k(G)$ is the set of $k$-matchings in $G$. Some examples of matchings or feasible association events are shown in Figure 4.

Now using the total probability theorem, we can compute the approximate distribution as:

$$
\hat{P}(X^k_t|y_{1:t}) := \sum_{\omega \in \Omega_t} \hat{P}(X^k_t|\omega, y_{1:t}) \hat{P}(\omega|y_{1:t})
$$

$$
= \sum_{j=0}^N \beta_{jk} \hat{P}(X^k_t|\omega_{jk}, y_{1:t}),
$$

(24)

where $\omega_{jk}$ denotes the event $\{\omega \in \Omega_t : (j, k) \in \omega\}$, $\omega_{0k}$ denotes the event that no observation is associated with target $k$, and $\beta_{jk}$ is an association probability, such that

$$
\beta_{jk} = \hat{P}(\omega_{jk}|y_{1:t}) = \sum_{\omega : (j,k) \in \omega} \hat{P}(\omega|y_{1:t}).
$$

(25)

$\hat{P}(X^k_t|\omega_{jk}, y_{1:t})$ in (24) can be easily computed by considering it as a single-target estimation problem with a single observation. On the other hand, the computation of $\beta_{jk}$ requires a summation over exponentially many association events.
Notice that even when linear–Gaussian models are assumed, the posterior (24) is no longer a Gaussian distribution. As explained earlier, the posterior (24) becomes a mixture of posteriors from the previous time step. Hence, the complexity of the posterior distribution grows exponentially in multi-target tracking due to uncertainty in measurement-to-target associations. To combat this growth, an assumed-density filter projects back to a fixed family at each step. In particular, JPDA approximates the posterior for each target using a moment-matching Gaussian distribution, and assumes that the targets are all independent.

The exact calculation of \( \{\beta_{jk}\} \) in JPDA is NP-hard [12] and this is the major drawback of JPDA. In the following sections, we describe the single-scan MCMCDA filter, which approximates the association probabilities \( \{\beta_{jk}\} \), and prove that the running time of the algorithm is polynomial in the size of the problem.

C. Single-Scan MCMCDA Filter

The single-scan MCMCDA filter follows the same filtering steps as the assumed-density single-scan Bayesian filter described in Section IV-B, except that the association probabilities \( \{\beta_{jk}\} \) in (25) are approximated using MCMC. Since the filtering steps are already described in Section IV-B, this section describes only the method of approximation.

Based on the parametric false alarm model described in Section II-A and a derivation similar to that of (7), for each \( \omega \in \Omega_t \), the prior \( P(\omega) \) can be written as

\[
P(\omega) \propto (\lambda_f V)^{N-|\omega|} |\omega|^{p \omega} (1 - p_d)^{K-|\omega|}.
\]  

(26)

Then, the posterior of \( \omega \in \Omega_t \) can be written as

\[
P(\omega|y_{1:t}) \overset{(a)}{=} \frac{1}{Z_0} P(\omega|y_{1:t-1}) P(y_t|\omega, y_{1:t-1})
\]

\[
\overset{(b)}{=} \frac{1}{Z_0} P(\omega) P(y_t|\omega, y_{1:t-1})
\]

\[
\overset{(c)}{=} \frac{1}{Z} P(\omega) \hat{P}(y_t|\omega, y_{1:t-1})
\]

\[
\overset{(d)}{=} \frac{1}{Z} \lambda_f^{N-|\omega|} p_d^{|\omega|} (1 - p_d)^{K-|\omega|} \prod_{(u,v) \in \omega} \hat{P}^v(u|y_{1:t-1})
\]

\[
= \hat{P}(\omega|y_{1:t}),
\]  

(27)

where \( Z_0 \) and \( Z \) are normalizing constants; Bayes rule is used in (a); (b) follows from the fact that \( \omega \in \Omega_t \) is independent of \( y_{1:t-1} \); (c) follows from the fact that \( \hat{P}(y_t|\omega, y_{1:t-1}) \) is an approximation of \( P(y_t|\omega, y_{1:t-1}) \); and the prior (26) is used in (d) and \( V^{N-|\omega|} \) is canceled by the matching false alarm density in \( \hat{P}(y_t|\omega, y_{1:t-1}) \).
The MCMC data association (MCMCDA) algorithm is an MCMC algorithm whose state space is the set of all feasible association events $\Omega_t$ and whose stationary distribution is the posterior $\hat{P}(\omega|y_{1:t})$ (27). The single-scan MCMCDA algorithm is shown in Algorithm 1 where $\theta = \{\hat{P}_v(u|y_{1:t−1})\}, \lambda_f, p_d, K, N$ along with its MCMC step described in Algorithm 2. The inputs to Algorithm 1 are the graph $G$, the number of samples $n_{mc}$, the number of burn-in samples $n_{bi}$, and $\theta$. The input $\theta$ contains likelihoods $\{\hat{P}_v(u|y_{1:t−1})\}$ and model parameters $\lambda_f, p_d, K, N$. Algorithm 1 computes the approximate association probabilities $\{\hat{\beta}_{jk}\}$, which can be used in (24) to compute the approximate posterior distribution $\hat{P}(X^k_t|y_{1:t})$. Algorithm 2 uses the MCMC transition rules from [13] and it describes how the MCMCDA algorithm updates its states. For the example given in Figure 3, the move from Figure 4(a) to Figure 4(b) is a switch move. The move from Figure 4(c) to Figure 4(b) is an addition move while its reverse is a deletion move. However, the move from Figure 4(a) to Figure 4(c) is not a legal single-step move according to Algorithm 2. Since we have a uniform proposal distribution, $A(\omega, \omega') = \min\left(1, \frac{\pi(\omega')}{\pi(\omega)}\right)$, where $\pi(\omega) = \hat{P}(\omega|y_{1:t})$ from (27).

Notice that, in line 2 of Algorithm 2 a self-loop transition probability of $1/2$ is introduced to make the analysis easier (see p.18 of [41] for more detail). In practice, however, the self-loop transition probability in line 2 can be set close to 0 for faster convergence.
Algorithm 2 Single-scan-MCMCDA.single-step

1: INPUT $G = (U, V, E), \omega, \theta$
2: OUTPUT $\omega$
3: sample $Z$ from Unif$[0, 1]$
4: if $Z < \frac{1}{2}$ then
5:   $\omega' = \omega$
6: else
7:   choose $e = (u, v) \in E$ uniformly at random
8:   if $e \in \omega$ then
9:     $\omega' = \omega - e$ (deletion move)
10: else if both $u$ and $v$ are unmatched in $\omega$ then
11:   $\omega' = \omega + e$ (addition move)
12: else if exactly one of $u$ and $v$ is matched in $\omega$ and $e'$ is the matching edge then
13:   $\omega' = \omega + e - e'$ (switch move)
14: else
15:   $\omega' = \omega$
16: end if
17: end if
18: $\omega = \omega'$ with probability $A(\omega, \omega')$

D. Analysis

Let $\mathcal{M}$ be the Markov chain simulated by Algorithm 2. Since the self-loop probability is nonzero, $\mathcal{M}$ is aperiodic. It can be easily seen that $\mathcal{M}$ is irreducible, i.e., all states communicate, for example via the empty matching. In addition, since Algorithm 2 uses the Metropolis-Hastings kernel, the detailed balance condition (13) is satisfied and $\mathcal{M}$ is reversible. Hence, by the ergodic theorem, the chain converges to its stationary distribution [34].

Let us first take a look at the complexity of the problem. As noted earlier, the state space of the Markov chain $\mathcal{M}$ is $\Omega_t = M_0(G) \cup \cdots \cup M_K(G)$. For each $k$, $|M_k(G)| \leq \binom{N^1}{k}$ with equality if the subgraph of $G$ with the $k$ chosen vertices in $V$ is a complete bipartite graph, i.e., all observations
are validated for all $k$ chosen targets. Hence, we can bound the size of $\Omega_t$ as
\begin{equation}
|\Omega_t| = |M_0(G)| + \cdots + |M_K(G)| \leq \sum_{k=0}^{K} \binom{K}{k} \frac{N!}{(N-k)!}.
\end{equation}
(28)

Except for trivial cases, the size of the state space grows exponentially as the number of targets or the number of observations increases, hence the exact calculation of JPDA by enumeration is not feasible when the number of targets or the number of observations is large. (See Section [IV-E] for experimental results.)

We assume that each likelihood term in (27) can be bounded as $L \leq \hat{P}^u(\omega_{1:t-1}) \leq \bar{L}$, for all $(u, v) \in E$. The lower bound $L = \min \delta^k$ is guaranteed by measurement validation. In JPDA, measurement validation is used to reduce the number of feasible association events. However, we will see that it is also required in the proof of polynomial-time approximation. The upper bound $\bar{L}$ can be precomputed based on $\hat{P}^u(\omega_{1:t-1})$. Here, we are making the reasonable assumption that $\hat{P}^u(\omega_{1:t-1}) \leq \bar{L} < \infty$ for all $(u, v) \in E$. (An example of $\bar{L}$ for linear–Gaussian models can be found in [42].)

The following theorems show that the single-scan MCMCDA algorithm provides a fully polynomial randomized approximation scheme for JPDA. See Appendix [VII-A] for the proof.

**Theorem 2:** Suppose that $\lambda_f > 0$ and $0 < p_d < 1$. Then the mixing time of the Markov chain $\mathcal{M}$ is bounded by
\begin{equation}
\tau(\epsilon) \leq 4R^4K^2N(m_0(K, N) + \log \epsilon^{-1})
\end{equation}
for all $\omega \in \Omega_t$, where
\begin{align*}
R & = \max \left\{ 1, \frac{p_d\bar{L}}{\lambda_f(1-p_d)}, \frac{\lambda_f(1-p_d)}{\bar{L}p_d} \right\}, \\
 m_0(K, N) & = K \log \frac{m_1}{m_2} + \log \frac{m_3(K, N)}{m_4(K, N)} + \sum_{k=1}^{K+1} \log k + \sum_{n=1}^{N} \log n \\
 m_1 & = \max\{1, \bar{L}\} \\
 m_2 & = \min\{1, \bar{L}\} \\
 m_3(K, N) & = \max_{0 \leq k \leq K} \left\{ \lambda_f^{N-k} p_d^k (1-p_d)^{K-k} \right\} \\
 m_4(K, N) & = \min_{0 \leq k \leq K} \left\{ \lambda_f^{N-k} p_d^k (1-p_d)^{K-k} \right\}
\end{align*}

**Remark 1:** If $0.5 < p_d < 1$ and $\lambda_f < 1 - p_d$, then $m_3(K, N) = \lambda_f^{N-K} p_d^K$ and $m_4(K, N) = \lambda_f^N (1-p_d)^K$. So $m_3(K, N)/m_4(K, N) = \left( \frac{p_d}{\lambda_f(1-p_d)} \right)^K$ and $K$ is the only remaining exponent.

**Remark 2:** Let $\bar{\tau}(\epsilon)$ be the upper bound found in Theorem 2. $\bar{\tau}(\epsilon)$ is polynomial in $K$ and $N$. If $m_3(K, N)/m_4(K, N)$ does not grow fast, e.g., Remark 1, $\bar{\tau}(\epsilon) = O(K^2N(K \log K + N \log N + \log \epsilon^{-1}))$. If $K$ is fixed, $\bar{\tau}(\epsilon) = O(N(N \log N + \log \epsilon^{-1}))$. 
Let \( p(\omega) \) be the distribution of the states of \( M \) after simulating Algorithm 2 for at least \( \bar{\tau}(\epsilon) \) steps. Then the total variation distance satisfies \( \| p - \pi \|_v \leq \epsilon \). So we can sample from \( p \) to estimate \( \{\beta_{jk}\} \). However, there is a small bias in our estimates since we are not sampling directly from \( \pi \). The following theorem gives an upper bound on the number of samples needed for finding good estimates. For the proof, see Appendix VII-B.

**Theorem 3:** Let \( 0 < \epsilon_1, \epsilon_2 \leq 1 \) and \( \beta \leq 0.5 \). Suppose that \( \| p - \pi \|_v \leq \epsilon \) for \( \epsilon \leq \epsilon_1 \epsilon_2 / 8 \). Then, with a total of \( 504 \epsilon_1^{-3} \epsilon_2^{-1} |\log \eta^{-1}| \) samples from \( p \), we can find estimates \( \hat{\beta}_{jk} \) for \( \beta_{jk} \) with probability at least \( 1 - \eta \), such that, for \( \beta_{jk} \geq \epsilon_2 \), \( \hat{\beta}_{jk} \) estimates \( \beta_{jk} \) within ratio \( 1 + \epsilon_1 \), i.e., \( (1 - \epsilon_1) \beta_{jk} \leq \hat{\beta}_{jk} \leq (1 + \epsilon_1) \beta_{jk} \), and, for \( \beta_{jk} < \epsilon_2 \), \( |\hat{\beta}_{jk} - \beta_{jk}| \leq (1 + \epsilon_1) \epsilon_2 \).

**Remark 3:** Following Remark 2, for fixed \( K \), \( \bar{\tau}(\epsilon) = O(N(\log N + \log \epsilon^{-1})) \). Combining this fact with Theorem 3, the time complexity of the overall procedure is

\[
\tilde{n}_{mc} = O(\epsilon_1^{-3} \epsilon_2^{-1} \log \eta^{-1} N(\log N + \log(\epsilon_1^{-1} \epsilon_2^{-1}))).
\]

Hence, with a total of \( \tilde{n}_{mc} \) samples, Algorithm 2 finds estimates \( \hat{\beta}_{jk} \) for \( \beta_{jk} \) with probability at least \( 1 - \eta \), such that, for \( \beta_{jk} \geq \epsilon_2 \), \( \hat{\beta}_{jk} \) estimates \( \beta_{jk} \) within ratio \( 1 + \epsilon_1 \), and, for \( \beta_{jk} < \epsilon_2 \), \( |\hat{\beta}_{jk} - \beta_{jk}| \leq (1 + \epsilon_1) \epsilon_2 \).

We can simplify further by letting \( \epsilon_0 = \epsilon_1 \epsilon_2 \). Then the time complexity is \( O(\epsilon_0^{-2} \log \eta^{-1} N(\log N + \log(\epsilon_0^{-1}))) \).

### E. Simulation Results

To demonstrate Theorem 3, we use a scenario in which there are five predicted observations and 16 actual observations over a \( 4 \times 4 \) two-dimensional region (see Figure 5(a)). The predicted observations are \( \{0, 3, 0, 1, 1, 0, 1, 0\} \) and the actual observations are

\[
\begin{bmatrix} 0.33, & -1.50, & -0.02, & -0.01, & -0.44, & 1.45, & -0.87, & 1.49 \\ 0.07, & 0.58, & -0.77, & -0.66, & -1.19, & -1.30, & -0.11, & -1.05 \\ -0.69, & -1.16, & -0.43, & -0.97, & 0.13, & -1.43, & 0.45, & 0.74 \\ 0.89, & 0.81, & -0.43, & -0.39, & -0.26, & 0.95, & -0.40, & 0.74 \end{bmatrix}
\]

\( \hat{P}^k(Y^j_t | y_{1:t-1}) \) has a Gaussian distribution with zero mean and covariance \( B^k = \text{diag}(1, 1) \) for all \( k \). The other parameters used in this simulation are: \( \lambda_f = 0.5, p_d = 0.8 \), and \( \delta^k = P((y^j_t - \hat{y}^j)^T(B^k)^{-1}(y^j_t - \hat{y}^j) = 4) \) for all \( k \).

The true values of \( \{\beta_{jk}\} \) are computed using JPDA. In order to study the convergence of the single-scan MCMCDA algorithm, we ran 100 independent runs with initial states randomly chosen from \( \Omega_t \). For each run, two types of estimates are made at each MCMC step: (type \( r = 1 \)) \( \hat{\beta}^1_{jk} \), which are computed after \( \bar{\tau}(\epsilon) \) burn-in samples; and (type \( r = 2 \)) \( \hat{\beta}^2_{jk} \), which are computed after 10,000 burn-in samples.
Fig. 5. (a) Predicted observations (crosses) and actual observations (dots). (b) The largest and smallest estimation ratios ($R^{r}$, $\bar{R}^{r}$) for two types of estimates ($r \in \{1, 2\}$) each computed from 100 independent single-scan MCMCDAs runs. The estimation ratios for $r = 1$ start from $\bar{\tau}(\epsilon) = 8.4 \times 10^6$ and the estimation ratios for $r = 2$ start from 10,000. The dotted $\epsilon_1$-tube centered at 1 represents the goal estimation ratio $\epsilon_1$. If $(R^{r}, \bar{R}^{r})$ is completely contained in $(1 - \epsilon_1, 1 + \epsilon_1)$, we have achieved our goal estimation ratio. Theoretically, $\bar{n}_{mc} = 11.5 \times 10^6$ samples suffice to ensure that the estimate using $\bar{\tau}(\epsilon)$ burn-in samples approximates the true value with ratio less than $\epsilon_1$ with probability at least $1 - \eta$. But both estimates achieve the estimation ratio of $\epsilon_1$ much faster than $\bar{n}_{mc}$.

Let $\hat{\beta}^{r}_{jk}(m, n)$ be the estimate made at the $n$th MCMC step for the $m$th run, for type $r \in \{1, 2\}$. Using $\epsilon_1 = 0.1$, $\epsilon_2 = 0.05$, $\eta = 0.05$, and $\epsilon = \epsilon_1\epsilon_2/8$, we have $\bar{\tau}(\epsilon) = 8.4 \times 10^6$.

Based on Theorem 3, $\bar{n}_{mc} = 11.5 \times 10^6$ samples suffice to ensure that the estimate using $\bar{\tau}(\epsilon)$ burn-in samples approximates the true value with ratio less than $\epsilon_1$ with probability at least $1 - \eta$. In order to show the progressive improvement of estimation ratios, we show the worst estimation ratios over all test cases as a function of the number of samples in Figure 5(b). Hence, if the worst estimation error ratios are within ratio less than $\epsilon_1$ after $\bar{n}_{mc}$ samples, i.e., the desired estimation ratio is satisfied for all test cases, it is certain that the statement of Theorem 3 is satisfied. Since there are upper and lower estimation ratio bounds in Theorem 3, we compute $\bar{R}^{r}(n)$, the largest estimation ratio, and $\bar{R}^{r}(n)$, the smallest estimation ratio over all test cases as a function of the number of samples and they are defined below.

Figure 5(b) shows a pair of envelopes, one for each type of estimate. The top curve of an envelope plots the largest estimation ratio over all $(j, k)$ pairs and all 100 runs

$$\bar{R}^{r}(n) = \max_{m=1, \ldots, 100} \max_{jk} \frac{\hat{\beta}^{r}_{jk}(m, n)}{\beta_{jk}}$$
and the bottom curve plots the smallest estimation ratio over all \((j, k)\) pairs and all 100 runs

\[
R^r(n) = \min_{m=1,\ldots,100} \min_{jk} \frac{\hat{\beta}^r_{jk}(m,n)}{\beta_{jk}}
\]

for \(r \in \{1, 2\}\), where \(n\) is the number of MCMC samples. The envelope for type \(r = 1\) starts from \(n = \bar{\tau}(\epsilon)\) and type \(r = 2\) starts from \(n = 10,000\).

A couple of observations can be made from Figure 5(b) The envelope \((R^1(n), \bar{R}^1(n))\) is completely contained in \((1 - \epsilon_1, 1 + \epsilon_1)\) for all \(n > \tilde{n}_{mc}\), hence, MCMCDA approximates the true value with ratio less than \(\epsilon_1\) with \(\tilde{n}_{mc} = 11.5 \times 10^6\) samples. Since the estimation ratios are satisfied for all test cases, they are certainly satisfied with probability at least \(1 - \eta\) and Theorem 3 is verified. Both types of estimates \((r = 1\) and \(r = 2\)) achieve the estimation ratio of \(\epsilon_1\) much faster than \(\tilde{n}_{mc}\). As frequently observed in many practical applications of MCMC, we see that the algorithm requires a significantly smaller number of burn-in samples than the theorem requires. This is not especially surprising since the theorem is based on a worst-case analysis. For this example, 10,000 burn-in samples were enough, i.e., 800 times less than \(\bar{\tau}(\epsilon)\).

In this example, JPDA took 134.1 seconds. With 10,000 burn-in samples, 95% of MCMCDA runs are within the goal approximation ratio of \(\epsilon_1\) in 33.9 seconds. Both algorithms are implemented in MATLAB on a PC with a 2.6-GHz Intel processor.

## V. Multi-Scan MCMCDA

The single-scan MCMCDA algorithm described in Section IV assumes a fixed, known number of targets. This assumption leads to a simple filtering scheme, but in most situations of interest the number of targets is unknown and changes over time. Furthermore, a single-scan algorithm that makes approximations (such as measurement validation and independence) to avoid complexity may end up being unable to maintain tracks over long periods because it cannot revisit previous, possibly incorrect, association decisions in the light of new evidence. For these reasons, methods for solving the general multi-target tracking problem described in Section II often adopt a multi-scan design, maintaining state in the form of both the posterior approximation and the observation history. This section describes a multi-scan MCMCDA algorithm that can handle unknown numbers of targets. The solution space \(\Omega\) for this algorithm contains association histories over multiple time steps, as well as considering all possible numbers of targets at each step, and is therefore much larger than the solution space considered by a single-scan algorithm. The multi-scan MCMCDA algorithm features efficient mechanisms to search over this large solution space in addition to birth and death moves to add or remove tracks. The multi-scan MCMCDA...
algorithm is presented in Section V-A and its recursive online version is described in Section V-B. In Section V-C, we compare the performance of MCMCDA against MHT and multi-scan NNF.

A. Multi-Scan MCMCDA Algorithm

The multi-scan MCMCDA algorithm is described in Algorithm 3. It is an MCMC algorithm whose state space is $\Omega$ as defined in Section II-B and whose stationary distribution is the posterior $\pi$. The proposal distribution for MCMCDA consists of eight moves grouped into five types as follows: (1) birth/death move pair; (2) split/merge move pair; (3) extension/reduction move pair; (4) track update move; and (5) track switch move. (See Figure 7.) We index each move by an integer such that $m = 1$ for a birth move, $m = 2$ for a death move and so on. The move $m$ is chosen randomly from the distribution $\xi_K(m)$ where $K$ is the number of tracks of the current partition $\omega$. When there is no track, we can only propose a birth move, so we set $\xi_0(m = 1) = 1$ and $0$ for all other moves. When there is only a single target, we cannot propose a merge or track switch move, so $\xi_1(m = 4) = \xi_1(m = 8) = 0$. For other values of $K$ and $m$, we assume $\xi_K(m) > 0$. The inputs for MCMCDA are the set of all observations $Y$, the number of samples $n_{mc}$, the initial state $\omega_{init}$, and the model parameters $p_z, p_d$, and $\lambda_b$. When we want to estimate $E_{\pi} f$ of a bounded function $f: \Omega \rightarrow \mathbb{R}^n$, MCMCDA can also take the function $f$ as an input. At each step of the algorithm, $\omega$ is the current state of the Markov chain. The acceptance probability $A(\omega, \omega')$ is defined in (12) where $\pi(\omega) = P(\omega|Y)$ from (9). Notice that MCMCDA can provide both Bayes estimator and MAP solutions to the multi-target tracking problem: the output $\hat{f}$ approximates the Bayesian posterior expectation $E_{\pi} f$ and $\hat{\omega}$ approximates the MAP estimate $\arg\max_{\omega \in \Omega} P(\omega|Y)$. The computation of $\hat{\omega}$ can be viewed as simulated annealing [43] at a constant temperature.

An MCMC algorithm can be specialized and made more efficient by incorporating domain-specific knowledge into the proposal distribution $q(\omega, \omega')$. For example, the MCMC algorithm by Pasula et al. [44] for citation matching incorporates a clustering method by McCallum et al. [45] to improve the performance of the algorithm. This method precomputes overlapping sets of “possibly matching” records and restricts the MCMC proposal distribution to consider associating record pairs only from these sets. This method prevents proposals that are certain to be rejected as impossible.

In multi-target tracking, we can make two assumptions: (A1) the maximum directional speed of any target in $\mathcal{R}$ is less than some $\bar{v}$; and (A2) the number of consecutive missing observations of any track is less than some $\bar{d}$. The first assumption (A1) is reasonable in a target-tracking scenario since, in many cases, the maximum speed of a vehicle is generally known based on the vehicle type and terrain conditions. We assume that the value of $\bar{v}$ is chosen large enough such that it accommodates measurement noise (e.g.,
Algorithm 3 Multi-scan-MCMCDA

1: INPUT $Y, n_{mc}, \omega_{\text{init}}, p_z, p_d, \lambda, f : \Omega \rightarrow \mathbb{R}^n$
2: OUTPUT $\hat{\omega}, \hat{f}$
3: $\omega = \omega_{\text{init}}$; $\hat{\omega} = \omega_{\text{init}}$; $\hat{f} = 0$
4: for $n = 1$ to $n_{mc}$ do
5: propose $\omega'$ based on $\omega$ (see sections V-A.1 to V-A.5)
6: sample $u$ from $\text{Unif}[0, 1]$
7: $\omega = \omega'$ if $u < A(\omega, \omega')$
8: $\hat{\omega} = \omega$ if $P(\omega|Y)/P(\hat{\omega}|Y) > 1$
9: $\hat{f} = \frac{n-1}{n} \hat{f} + \frac{1}{n} f(\omega)$
10: end for

adding a multiple of the standard deviation of the measurement noise). The second assumption (A2) is a user-defined parameter. Let $p_{\text{dt}}(s) = 1 - (1 - p_d)^s$ be the probability that an object is observed at least once out of $s$ measurement times. Then, for given $p_{\text{dt}}$, we set $d \geq \log(1 - p_{\text{dt}})/\log(1 - p_d)$ to detect a track with probability at least $p_{\text{dt}}$. For example, given $p_d = 0.7$ and $p_{\text{dt}} = 0.99$, a track is detected with probability larger than 0.99 for $d \geq 4$. We will now assume that these two new conditions (A1–2) are added to the definition of $\Omega$ so each element $\omega \in \Omega$ satisfies these two additional assumptions. In the following description of the multi-scan MCMCDA algorithm, we also assume that a track contains at least two measurements for computational efficiency.

According to (A1–2), we can determine whether two measurements at different times can be generated from the same target or not. For example, see Figure 6. Let’s consider $y_1^1$ in Figure 6 a measurement made at $t = 1$. If $y_1^1$ is a measurement from a target, then a measurement of this target at time $t = 2$ must be in the range denoted by $d = 1$ centered at $y_1^1$. Hence, $y_2^1$ can be a measurement from this target while $y_2^2$ cannot be a measurement from this target. We formalize this concept into the following data structure.

Let $L(y, t, d)$ be a set of all measurements at time $t + d$ that can be associated with a measurement $y \in \mathbb{R}^{n_y}$, i.e.,

$$L(y, t, d) = \{ y_{t+d}^k \in y_{t+d} : \varphi(y, y_{t+d}^k) \leq d \cdot \bar{v} \},$$

where $d \in \{1, \ldots, d\}$, and $\varphi : \mathbb{R}^{n_y} \times \mathbb{R}^{n_y} \rightarrow \mathbb{R}$ is an appropriate metric, e.g., for a Cartesian coordinate system, $\varphi$ is induced by the Euclidean norm.

For our example shown in Figure 6 $L(y_1^1, t = 1, d = 1) = \{ y_2^1 \}$, $L(y_1^1, t = 1, d = 2) = \{ y_3^1 \}$, and
Suppose that the measurement $y_t$ is generated from a target. A measurement of this target at time $t = 2$ must be in the range denoted by $d = 1$ centered at $y_1$. A measurement of this target at time $t = 3$ must be in the range denoted by $d = 2$ centered at $y_1$. A measurement of this target at time $t = 4$ must be in the range denoted by $d = 3$ centered at $y_1$. If $d = 3$, there cannot be a track whose measurements are only $y_1^1$ and $y_1^2$ (or $y_1^1$ and $y_2^2$) since such track contains 4 consecutive missing measurements.

$L(y_1^1, t = 1, d = 3) = \{y_1^1, y_2^2\}$. The use of $L(y, t, d)$ makes the algorithm more scalable since distant observations will be considered separately and makes the computation of the proposal distribution easier. It is similar to the gating technique used in MHT but $L(y, t, d)$ in MCMCDA is fixed for a given set of observations. We fix $L(y, t, d)$ so that the proposal distribution $q(\omega, \omega')$ can be computed consistently.

We now describe each move of the sampler in detail. First, let $\zeta(d)$ be a distribution of a random variable $d$ taking values from $\{1, 2, \ldots, d\}$. We assume the current state of the chain is $\omega = \omega^0 \cup \omega^1 \in \Omega$, where $\omega^0 = \{\tau_0\}$ and $\omega^1 = \{\tau_1, \ldots, \tau_K\}$. The proposed partition is denoted by $\omega' = \omega^0 \cup \omega'^1 \in \Omega$. The proposal distribution $q(\omega, \omega')$ can be computed by keeping track of how $\omega$ is modified to form $\omega'$. Note the abuse of notation below with indexing of time, i.e., when we say $\tau(t_i)$, $t_i$ means the time at which a target corresponding to the track $\tau$ is observed $i$ times.

1) Birth and Death Moves (Figure 7, $a \leftrightarrow b$): For a birth move, we increase the number of tracks from $K$ to $K' = K + 1$ and select $t_1$ uniformly at random (u.a.r.) from $\{1, \ldots, T - 1\}$ as the appearance time of a new track. Let $\tau_{K'}$ be the track of this new object. Then we choose $d_1$ from the distribution $\zeta$. Let $L^B(t_1, d_1) = \{y_{t_1}^d \in y_t : L(y_{t_1}^d, t_1, d_1) \neq \emptyset, y_{t_1}^d \not\in \tau_k(t_1), k = 1, \ldots, K\}$. $L^B(t_1, d_1)$ is a set of observations at $t_1$ such that $y \in L^B(t_1, d_1)$ does not belong to other tracks and $L(y, t_1, d_1)$ is not empty. We choose $\tau_{K'}(t_1)$ u.a.r. from $L^B(t_1, d_1)$. If $L^B(t_1, d_1)$ is empty, the move is rejected since the move is not reversible. Once the initial observation is chosen, we then choose the subsequent observations for the track $\tau_{K'}$. For $i = 2, 3, \ldots$, we choose $d_i$ from $\zeta$ and choose $\tau_{K'}(t_i)$ u.a.r. from $L(\tau_{K'}(t_{i-1}), t_{i-1}, d_i)$ \(\backslash\)
Fig. 7. Graphical illustration of MCMCDA moves (associations are indicated by dotted lines and hollow circles are false alarms). Each move proposes a new joint association event $\omega'$ that is a modification of the current joint association event $\omega$. The birth move proposes $\omega'$ by forming a new track from the set of false alarms ((a) $\rightarrow$ (b)). The death move proposes $\omega'$ by combining one of the existing tracks into the set of false alarms ((b) $\rightarrow$ (a)). The split move splits a track from $\omega$ into two tracks ((c) $\rightarrow$ (d)) while the merge move combines two tracks in $\omega$ into a single track ((d) $\rightarrow$ (c)). The extension move extends an existing track in $\omega$ ((e) $\rightarrow$ (f)) and the reduction move reduces an existing track in $\omega$ ((f) $\rightarrow$ (e)). The track update move chooses a track in $\omega$ and assigns different measurements from the set of false alarms ((g) $\leftrightarrow$ (h)). The track switch move chooses two track from $\omega$ and switches some measurement-to-track associations ((i) $\leftrightarrow$ (j)).

$\{\tau_k(t_{i-1} + d_i) : k = 1, \ldots, K\}$ unless this set is empty. But, for $i = 3, 4, \ldots$, the process of adding observations to $\tau_{K'}$ terminates with probability $\gamma$, where $0 < \gamma < 1$. If $|\tau_{K'}| \leq 1$, the move is rejected. We then propose this modified partition where $\omega' = \omega^1 \cup \{\tau_{K'}\}$ and $\omega^0 = \{\tau_0 \setminus \tau_{K'}\}$. For a death move, we simply choose $k$ u.a.r. from $\{1, \ldots, K\}$ and delete the $k^{th}$ track and propose a new partition where $\omega' = \omega^1 \setminus \{\tau_k\}$ and $\omega^0 = \{\tau_0 \setminus \tau_k\}$.

2) Split and Merge Moves (Figure 7, c $\leftrightarrow$ d): For a split move, we select $\tau_s(t_r)$ u.a.r. from $\{\tau_k(t_i) : |\tau_k| \geq 4, i = 2, \ldots, |\tau_k| - 2, k = 1, \ldots, K\}$. Then we split the track $\tau_s$ into $\tau_{s_1}$ and $\tau_{s_2}$ such that $\tau_{s_1} = \{\tau_s(t_i) : i = 1, \ldots, r\}$ and $\tau_{s_2} = \{\tau_s(t_i) : i = r + 1, \ldots, |\tau_s|\}$. The modified track partition becomes $\omega' = (\omega^1 \setminus \{\tau_s\}) \cup \{\tau_{s_1}\} \cup \{\tau_{s_2}\}$ and $\omega^0 = \omega^0$. For a merge move, we consider the following set of possible merge move pairs:

$$M = \{(\tau_{k_1}(t_f), \tau_{k_2}(t_1)) : \tau_{k_2}(t_1) \in L(\tau_{k_1}(t_f), t_f, t_1 - t_f),$$

$$f = |\tau_{k_1}| \text{ for } k_1 \neq k_2, 1 \leq k_1, k_2 \leq K\}.$$

We select a pair $(\tau_{s_1}(t_f), \tau_{s_2}(t_1))$ u.a.r. from $M$. The tracks are combined into a single track $\tau_s = \tau_{s_1} \cup \tau_{s_2}$. Then we propose a new partition where $\omega' = (\omega^1 \setminus \{\tau_{s_1}\}) \cup \{\tau_{s_2}\}$ and $\omega^0 = \omega^0$. 
3) Extension and Reduction Moves (Figure 7, \(e \leftrightarrow f\)): In a track extension move, we select a track \(\tau\) u.a.r. from \(K\) available tracks in \(\omega\). We reassign observations for \(\tau\) after the disappearance time \(t_{\mid \tau}\) as done in the track birth move. For a track reduction move, we select a track \(\tau\) u.a.r. from \(K\) available tracks in \(\omega\) and \(r\) u.a.r. from \(\{2, \ldots, |\tau| - 1\}\). We shorten the track \(\tau\) to \(\{\tau(t_1), \ldots, \tau(t_r)\}\) by removing the observations assigned to \(\tau\) after the time \(t_{r+1}\).

4) Track Update Move (Figure 7, \(g \leftrightarrow h\)): In a track update move, we select a track \(\tau\) u.a.r. from \(K\) available tracks in \(\omega\). Then we pick \(r\) u.a.r. from \(\{1, 2, \ldots, |\tau|\}\) and reassign observations for \(\tau\) after the time \(t_r\) as done in the track birth move.

5) Track Switch Move (Figure 7, \(i \leftrightarrow j\)): For a track switch move, we select a pair of observations \((\tau_{k_1}(t_p), \tau_{k_2}(t_q))\) from two different tracks such that, \(\tau_{k_1}(t_{p+1}) \in L(\tau_{k_2}(t_q), t_q, d)\) and \(\tau_{k_2}(t_{q+1}) \in L(\tau_{k_1}(t_p), t_p, d')\), where \(d = t_{p+1} - t_q, d' = t_{q+1} - t_p\) and \(0 < d, d' \leq \bar{d}\). Then we let

\[
\begin{align*}
\tau_{k_1} &= \{\tau_{k_1}(t_1), \ldots, \tau_{k_1}(t_p), \tau_{k_2}(t_{q+1}), \ldots, \tau_{k_2}(t_{|\tau_{k_2}|})\} \\
\tau_{k_2} &= \{\tau_{k_2}(t_1), \ldots, \tau_{k_2}(t_q), \tau_{k_1}(t_{p+1}), \ldots, \tau_{k_1}(t_{|\tau_{k_1}|})\}.
\end{align*}
\]

The main result of this section is that MCMCDA is an optimal Bayesian filter in the limit. Let \(\mathcal{M}\) be the Markov chain specified by Algorithm 3. Then we have:

**Theorem 4:** Suppose that \(0 < p_x, p_d < 1\) and \(\lambda_b, \lambda_f > 0\). If \(\zeta(d) > 0\) for all \(d \in \{1, \ldots, \bar{d}\}\), then the Markov chain \(\mathcal{M}\) is ergodic and \(\hat{f} \to \mathbb{E}_\pi f\) as \(n_{mc} \to \infty\).

See Appendix VII-C for the proof of the theorem. For a numerical demonstration of the theorem, see Section V-C.5.

**B. Online MCMCDA**

The MCMCDA algorithm described in previous section is a batch algorithm and its computational complexity grows as more measurements are collected. In filtering, since recent measurements are more relevant to the current states, good estimates of the current states can still be found from recent measurements [46]. Based on this idea, we propose an online MCMCDA algorithm whose estimates are based on measurements from a window of time \([t_{\text{cur}} - t_{\text{win}} + 1, \ldots, t_{\text{cur}}]\), where \(t_{\text{cur}}\) is the current time and \(t_{\text{win}}\) is the size of a window. Hence, at all times, only finitely many measurements are kept by the algorithm. This online implementation of MCMCDA, shown in Algorithm 4, is suboptimal because it considers only a subset of past measurements.

At each time step, we use the previous MAP estimate to initialize MCMCDA and run MCMCDA on the measurements \(Y_w(t_{\text{cur}}) = \{y_t^j : 1 \leq j \leq n_t, t_{\text{cur}} - t_{\text{win}} + 1 \leq t \leq t_{\text{cur}}\}\) belonging to the current window. At time \(t_{\text{cur}}\), the measurements at time \(t_{\text{cur}} - t_{\text{win}}\) are removed from \(Y_w\) and a set of newly
Algorithm 4 Online-MCMCDA (at time $t_{\text{cur}}$)

1: INPUT: $\hat{\omega}(t_{\text{cur}} - 1)$, $Y_w(t_{\text{cur}} - 1)$, $Y_{\text{new}}(t_{\text{cur}})$, $n_{\text{mc}}$, $p_z$, $p_d$, $\lambda_b$, $f : \Omega \rightarrow \mathbb{R}^n$

2: OUTPUT: $\hat{\omega}(t_{\text{cur}})$, $Y_w(t_{\text{cur}})$, $\hat{f}(t_{\text{cur}})$

3: $Y_w(t_{\text{cur}}) = \{y^j_t \in Y_w(t_{\text{cur}} - 1) : t_{\text{cur}} - t_{\text{win}} + 1 \leq t_{\text{cur}}\}$

4: add new measurements $Y_{\text{new}}(t_{\text{cur}})$ into $Y_w(t_{\text{cur}})$

5: $\omega_{\text{init}} = \{\tau(t) \in \hat{\omega}(t_{\text{cur}} - 1) : t_{\text{cur}} - t_{\text{win}} + 1 \leq t_{\text{cur}}\}$

6: $[\hat{\omega}(t_{\text{cur}}), \hat{f}(t_{\text{cur}})] = \text{Multi-scan-MCMCDA}(Y_w(t_{\text{cur}}), n_{\text{mc}}, \omega_{\text{init}}, p_z, p_d, \lambda_b, f)$ (see Algorithm 3)

arrived measurements $Y_{\text{new}}(t_{\text{cur}})$ is appended to $Y_w(t_{\text{cur}})$. Any delayed measurements are inserted into the appropriate slots. Then, we initialize the Markov chain with the previously estimated tracks and execute Algorithm 3 on $Y_w(t_{\text{cur}})$. The algorithm is summarized in Algorithm 4. The inputs for online MCMCDA at time $t_{\text{cur}}$ are the previous MAP estimate $\hat{\omega}(t_{\text{cur}} - 1)$, the existing set of measurements $Y_w(t_{\text{cur}} - 1)$, and the set of new measurements $Y_{\text{new}}(t_{\text{cur}})$. The other inputs are the same as Algorithm 3. Other estimates such as state estimates can be computed using the function $f$ or $\hat{\omega}(t_{\text{cur}})$. Simulation results from online MCMCDA can be found in Section V-C.4.

C. Simulation Results

In this section, the performance of multi-scan MCMCDA is evaluated and compared against MHT [47] and multi-scan NNF [48]. We consider surveillance over a rectangular region on a plane, $\mathcal{R} = [0, 1000] \times [0, 1000]$. The state vector is $x = [x, y, \dot{x}, \dot{y}]^T$ where $(x, y)$ is a position on $\mathcal{R}$ along the usual $x$ and $y$ axes and $(\dot{x}, \dot{y})$ is a velocity vector. Linear dynamics and a linear measurement model are used:

$$x^k_{t+1} = Ax^k_t + Gw^k_t$$
$$y^j_t = Cx^k_t + v^j_t$$

(30)

where

$$A = \begin{bmatrix}
1 & 0 & T_s & 0 \\
0 & 1 & 0 & T_s \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{bmatrix}, \quad G = \begin{bmatrix}
T_s^2/2 & 0 \\
0 & T_s^2/2 \\
T_s & 0 \\
0 & T_s
\end{bmatrix},$$

$$C = \begin{bmatrix}
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0
\end{bmatrix}, \quad T_s \text{ is the sampling period, } w^k_t \text{ is a zero-mean Gaussian process with covariance } Q = \text{diag}(100, 100), \text{ and } v^j_t \text{ is a zero-mean Gaussian process with covariance } R = \text{diag}(100, 100).$$

The complexity of multi-target tracking problems can be measured by several metrics: (1) the intensity of the false alarm rate $\lambda_f$; (2) the detection probability $p_d$; and (3) the density of tracks. The problem
gets more challenging with increasing $\lambda_f$, decreasing $p_d$, and increasing density of tracks. The number of tracks *per se* may not make the problem more difficult if they are scattered apart; the difficulty arises when there are many tracks crossing and moving close to each other; this is when the ambiguity of data association is greatest. Hence, we consider only situations in which tracks move very closely so we can control the density of tracks by the number of tracks.

We study the performance of the MCMCDA algorithm against multi-scan NNF and MHT by varying the parameters listed above. To make the comparison easier, we take the MAP approach, in which the states of targets are estimated from $\hat{\omega}$ computed from Algorithm 3. The multi-scan NNF algorithm is a batch-mode, nearest-neighbor, multi-target tracking algorithm. Initially, all observations are unmarked. Unmarked observations are considered false alarms. The algorithm first picks two unmarked observations at different times to estimate an initial state. Then it forms a candidate track by picking the unmarked observations for the subsequent time step that are closest to the predicted states. The candidate track is validated as a track and observations associated to the candidate track are marked if the marginal of the candidate track exceeds a threshold. The process is repeated until no more tracks can be found. For a more detailed description of the multi-scan NNF algorithm, see [48].

Based on our model described above and in Section II, we have generated a variety of scenarios. In particular, in all cases, except for the online tracking case, half of the new objects appear from the bottom left quadrant of $R$ and the other half appear from the the bottom right quadrant. (The actual initial positions are chosen randomly from a $200 \times 200$ region in each quadrant.) They all move diagonally so that each group of tracks crosses the other group in the middle of $R$. The targets also move very close to each other and there are crossovers within each group. All targets are present from $t = 1$ to $t = T$. In order to measure the density of tracks, the distance between every pair of targets at each time is computed from a test case ($K = 100$) used in Section V-C.1. Then, for each target, the numbers of neighboring targets are counted at different target-to-target distance ranges with an interval of 50. Figure 8(a) shows the mean number of neighboring targets at different distance ranges while Figure 8(b) shows the maximum number of neighboring targets at different distance ranges. In this example, at $t = 5$, the mean number of neighboring targets with distance less than 50 is 13 and some targets have 25 neighboring targets. For distance less than 100, the mean number of neighboring targets is 42 and some targets have 73 neighboring targets. Based on the dynamics and measurement noise models (30), the effective overall standard deviation in two dimension is 28.3. Hence, the distance of 100 is 3.5 times the effective standard deviation.

Since the number of targets is not fixed, it is difficult to compare algorithms using a standard criterion
such as the mean squared error. Instead, we use a performance measure, called $F_1$, which is frequently used in the information retrieval literature \cite{49} and has been used in particular for evaluating data-association-like methods in record matching \cite{50}. The $F_1$ measure is defined in terms of recall and precision. Recall is the ratio of correct associations made by an algorithm divided by the total number of correct associations. Precision is the ratio of correct associations made by an algorithm divided by the total number of associations made by the algorithm. The $F_1$ measure is a harmonic mean between recall ($r$) and precision ($p$) with an equal weight and defined as:

$$F_1(r, p) = \frac{2rp}{r + p}.$$ \hfill (31)

Recall and precision measure the effectiveness of an algorithm \cite{49}; the higher the value of the $F_1$ measure, the more effective the algorithm is.

Both MCMCDA and multi-scan NNF algorithms are written in C++ with MATLAB interfaces. We have used the C++ implementation of MHT \cite{47}, which implements pruning, gating, clustering, $N$-scan-back logic and $k$-best hypotheses. The parameters for MHT are fine-tuned so that it gives similar performance to that of MCMCDA when there are 10 targets: the maximum number of hypotheses in a group is 1,000, the maximum track tree depth is 5, and the maximum Mahalanobis distance is 11.8. All simulations are run on a PC with a 2.6-GHz Intel processor.

1) Number of Tracks: In this experiment, we vary $K$ from 10 to 100. The other parameters are held fixed: $\mathcal{R} = [0, 1000] \times [0, 1000], T = 10, p_d = 0.9, \lambda_f V = 1, \lambda_b V = K/T, p_z = .0001, \bar{d} = 5, \bar{v} = 100$
unit lengths per unit time. A uniform mass function is used for each $\xi_k(\cdot)$ and $\zeta(d)$ is computed based on $p_d$. For each value of $K$, we randomly generated 10 test cases. The initial state of MCMCDA is computed using the multi-scan NNF algorithm and 50,000 samples are used in MCMCDA. For each $K$, the average $F_1$ measure and running time are computed from the 10 test cases (for MCMCDA, we also average over 10 runs per test case). The average $F_1$ measure computed at each value of $K$ is shown in Figure 9(a). The average running times of the three algorithms are shown in Figure 9(b) (the running time of MCMCDA includes the initialization step). Although the maximum number of hypotheses of 1,000 per group is a large number, with increasing numbers of tracks, the performance of MHT deteriorates due to pruning. The $F_1$ measure for multi-scan NNF is just above 0.5 even when there are only ten targets. MCMCDA shows superior performance against both MHT and multi-scan NNF. In this example, the multi-scan NNF performs better than MHT at higher numbers of targets. This is due to the fact that all targets are present from $t = 1$ to $t = T$. Another striking difference is that the running times of both multi-scan NNF and MCMCDA are significantly less than that of MHT.
2) **False Alarms:** Now the settings are the same as Section V-C.1 but we vary the false alarm rate while the number of tracks is fixed at $K = 10$. The false alarm rate is varied from $\lambda_f V = 1$ to $\lambda_f V = 100$ with an increment of 10. For each value of $\lambda_f V$, we randomly generated 10 test cases and MCMCDA is run 10 times per test case. Again, 50,000 samples are used for MCMCDA. The average $F_1$ measures for the three algorithms at different false alarm rates are given in Figure 9(c). The results show that MCMCDA performs well at high false alarm rates. The multi-scan NNF algorithm suffers because it finds too many spurious tracks (poor precision) and MHT becomes hopelessly confused, finding no correct associations at $\lambda_f V \geq 80$.

3) **Detection Probability:** The detection probability $p_d$ is varied from 0.3 to 0.99 with an increment of 0.1, except the last increment which is 0.09, while keeping the other parameters as in the previous experiments except $K = 10$ and $\lambda_f V = 1$. For each value of $p_d$, we randomly generated 10 test cases and MCMCDA is run 10 times per test case. Again, 50,000 samples are used for MCMCDA. The average $F_1$ measures for three different algorithms at different detection probabilities are shown in Figure 9(d). The overall performance of MCMCDA is better than that of MHT. MHT only performs slightly better than MCMCDA at $p_d = 0.99$. The running times of both MCMCDA and MHT are comparable in this case (MCMCDA was about 1 second faster than MHT for all cases except when $p_d = 0.99$). The multi-scan NNF algorithm performed very poorly.

Although, in theory, MHT gives an optimal solution in the sense of MAP, it performs poorly in practice when the detection probability is low or the false alarm rate is high. This is due to the heuristics, such as pruning and $N$-scan-back techniques, that are required to limit complexity. They work well when a few hypotheses carry most of the weight. (This is why MHT performed slightly better than MCMCDA when $p_d = 0.99$.) When the detection probability is low or the false alarm rate is high, however, there are many hypotheses with appreciable weights and there is no small set of dominating hypotheses, so MHT cannot perform well. A major advantage of the MCMCDA algorithm is that its running time can be regulated by the number of samples and the number of observations but the running time of MHT depends on the complexity of the problem instance, which is not predictable in advance. In addition, the memory required by MCMCDA is significantly less than the memory required by MHT, since MCMCDA is only required to store one association event at a time.

4) **Online MCMCDA:** An example of tracking multiple targets in a densely cluttered environment is used to demonstrate online MCMCDA from Section V-B. For this example, the surveillance duration is $T = 100$ and the scenario is generated according to the model for multi-target tracking described in Section II-A. The surveillance region is $\mathcal{R} = [0, 100] \times [0, 100]$ and the model parameters are: $\lambda_b V = 5$, $\lambda_f V = 1$, and $\lambda_b V = 5$. The results show that online MCMCDA performs well in this scenario.
$p_z = 1/20$, $p_d = 0.7$, and $\lambda_f V = 30$. There are a total of 380 targets. The linear model (30) is used, but with different covariance matrices: $Q = \text{diag}(0.031, 0.031)$ and $R = \text{diag}(0.031, 0.031)$. The size of the sliding window is $t_{\text{win}} = 14$ for the online MCMCDA algorithm while $\bar{d} = 5$ and $\bar{v} = 3$ unit lengths per unit time.

For this example, MHT took 6,995 seconds while online MCMCDA took only 343 seconds, i.e., a 20-fold reduction in computation time. On the $F_1$ measure, MHT scored 0.85 and MCMCDA scored 0.91. In addition, MHT found 494 targets but MCMCDA detected 335 targets which is close to the actual number of 380 targets. The tracks estimated by MHT and MCMCDA are shown in Figure 10. For easy comparison, Figure 10 also shows the actual trajectories of targets. In summary, this example shows that MCMCDA is very effective in a dense environment and achieves superior performance with a fraction of the computation time required by MHT.

5) Convergence: An example is used to demonstrate the convergence of MCMCDA (Theorem 4). In order to compute the exact estimates, we have chosen a simple example where there are four scans ($T = 4$) and three measurements per scan. Hence, there are a total of 12 measurements. But even for this simple case, there are over 45,000 partitions or association events, i.e., the size of $\Omega$ is over 45,000. We again used the dynamics and measurement model given in (30), where $Q = \text{diag}(4, 4)$ and $R = \text{diag}(4, 4)$. The surveillance region is $\mathcal{R} = [0, 100] \times [0, 100]$. The other parameters are: $p_d = 0.7$, $\lambda_f = 0.0013$, $\lambda_b = 9.38 \times 10^{-4}$, $\bar{d} = 4$, and $\bar{v} = 100$. All the measurements are shown in Figure 11(a) and they are

$Y_1 = \left\{ \begin{bmatrix} 7.81 \end{bmatrix}, \begin{bmatrix} 9.46 \end{bmatrix}, \begin{bmatrix} 7.92 \end{bmatrix} \right\}$, $Y_2 = \left\{ \begin{bmatrix} 28.93 \end{bmatrix}, \begin{bmatrix} 29.88 \end{bmatrix}, \begin{bmatrix} 27.31 \end{bmatrix} \right\}$, $Y_3 = \left\{ \begin{bmatrix} 51.30 \end{bmatrix}, \begin{bmatrix} 51.91 \end{bmatrix}, \begin{bmatrix} 52.04 \end{bmatrix} \right\}$, $Y_4 = \left\{ \begin{bmatrix} 70.58 \end{bmatrix}, \begin{bmatrix} 75.70 \end{bmatrix}, \begin{bmatrix} 66.71 \end{bmatrix} \right\}$.

Let $A$ be an event such that there are 3 targets at time $t = T$ and $X^k$ be the state of the $k^{th}$ target at time $t = T$. Let $B$ be an event such that $B \subset A$ and $\|X^1\| < \|X^2\| < \|X^3\|$. Our objective is the computation of $\mathbb{E}(X^k|B)$ for $k = 1, 2, 3$. Here, $B$ provides a unique labeling with probability 1. Values for $\mathbb{E}(X^k|B)$ are computed exactly by enumeration. Let $\hat{X}^k(n)$ be the estimate of $\mathbb{E}(X^k|B)$ made at the $n^{th}$ MCMC step of Algorithm 3 after the first 100 burn-in samples. We ran 100 independent runs and computed the root mean-square error (RMSE) for each $k$ and $n$. The average RMSE is shown as a function of the number of samples in Figure 11(b). Although the size of the partition space $\Omega$ is over 45,000, this is a simple case and, as one might expect. Figure 11(b) shows rapid convergence of MCMCDA estimates toward the exact values.
Fig. 10. Actual trajectories of targets at different time intervals and tracks estimated by MHT and MCMCDA. The running time of MCMCDA for this example was 343 seconds while it took 6,995 seconds for MHT to complete. MCMCDA scored 0.91 in the $F_1$ measure and MHT scored 0.85. (a) Actual trajectories of targets from $t = 10$ to $t = 40$. (b) Tracks estimated by MHT from $t = 10$ to $t = 40$. (c) Tracks estimated by MCMCDA from $t = 10$ to $t = 40$. (d) Actual trajectories of targets from $t = 40$ to $t = 70$. (e) Tracks estimated by MHT from $t = 40$ to $t = 70$. (f) Tracks estimated by MCMCDA from $t = 40$ to $t = 70$. (g) Actual trajectories of targets from $t = 70$ to $t = 100$. (h) Tracks estimated by MHT from $t = 70$ to $t = 100$. (i) Tracks estimated by MHT from $t = 70$ to $t = 100$. 
VI. CONCLUSIONS

In this paper, we have presented Markov chain Monte Carlo data association (MCMCDA) for solving data association problems arising in multi-target tracking in a cluttered environment. Instead of enumerating the entire space of associations, MCMCDA randomly samples the region where the posterior is concentrated.

For the case of a fixed number of targets, we have shown that a single-scan MCMCDA algorithm provides a fully polynomial randomized approximation scheme for the JPDA calculation, which is known to be NP-hard and is infeasible in practice for large problems. One can also consider a combined approach, where JPDA is used for small subgraphs created after some of the edges in the bipartite measurement validation graph have been broken by MCMC sampling. The precise division of labor will depend on the specific application and available computing resources.

For the general multi-target tracking problem, in which unknown numbers of targets appear and disappear at random times, we have presented a multi-scan MCMCDA algorithm that is capable of initiating and terminating tracks. Our simulation results show the remarkable performance of the MCMCDA algorithm under extreme conditions such as a large number of targets in a dense environment, low detection probabilities, and high false alarm rates. The MCMCDA algorithm is flexible and can easily incorporate domain specific knowledge to make it more efficient. The efficiency of MCMCDA has been
demonstrated as part of the real-time control system developed for solving multi-agent pursuit-evasion game using a large-scale outdoor wireless sensor network [5].

VII. APPENDIX

A. Proof of Theorem 2

To prove Theorem 2 we need the following lemmas. For notational convenience, we denote \( \Omega_t \) by \( \Omega \).

**Lemma 1:** Let \( C = \frac{\rho_0 L}{\lambda_f(1-p_d)} \) and \( D = \frac{\lambda_f(1-p_0)}{Lp_d} \). For any \( \omega_0, \omega_1, \omega_2 \in \Omega \), if \( \omega_1 = \omega_0 - e_0 \), for some edge \( e_0 \in \omega_0 \), and \( \omega_2 = \omega_1 - e_1 \), for some edge \( e_1 \in \omega_1 \), then:

\[
\frac{\pi(\omega_0)}{\pi(\omega_1)} \leq C \quad \text{and} \quad \frac{\pi(\omega_1)}{\pi(\omega_0)} \leq D
\]

\[
\frac{\pi(\omega_0)}{\pi(\omega_2)} \leq C^2 \quad \text{and} \quad \frac{\pi(\omega_2)}{\pi(\omega_0)} \leq D^2.
\]

**Proof:** \( \omega_0 \) and \( \omega_1 \) are identical except that \( \omega_1 \) is missing the edge \( e_0 \). So \( |\omega_0| = |\omega_1| + 1 \). If \( e_0 = (u, v) \) and \( k = |\omega_0| \),

\[
\frac{\pi(\omega_0)}{\pi(\omega_1)} = \frac{\lambda_f^{N-k} p_0^k (1-p_d)^{K-k}}{\lambda_f^{N-(k-1)} p_d^{k-1} (1-p_d)^{K-(k-1)}} \hat{P}^v(u|y_{1:t-1})
\]

\[
= \frac{p_d}{\lambda_f(1-p_d)} \hat{P}^v(u|y_{1:t-1}) \leq C.
\]

On the other hand,

\[
\frac{\pi(\omega_1)}{\pi(\omega_0)} = \frac{\lambda_f^{N-(k-1)} p_d^{k-1} (1-p_d)^{K-(k-1)}}{\lambda_f^{N-k} p_0^k (1-p_d)^{K-k}} \frac{1}{\hat{P}^v(u|y_{1:t-1})}
\]

\[
= \frac{\lambda_f(1-p_d)}{p_d} \frac{1}{\hat{P}^v(u|y_{1:t-1})} \leq D.
\]

Since \( \frac{\pi(\omega_0)}{\pi(\omega_2)} = \pi(\omega_0)/\pi(\omega_1) \times \pi(\omega_1)/\pi(\omega_2) \), by repeating the above argument twice, we get \( \pi(\omega_0)/\pi(\omega_2) \leq C^2 \). Similarly, we have \( \pi(\omega_2)/\pi(\omega_0) \leq D^2 \).

**Lemma 2:** Let \( R = \max\{1, C, D\} \), where \( C \) and \( D \) are defined in Lemma 1. Then the maximum edge loading of the Markov chain \( \mathcal{M} \) is bounded as \( \bar{\rho} \leq 4R^4K^2N \).

**Proof:** For each pair of matchings \( X, Y \) in \( G \), we define the canonical path \( \gamma_{XY} \) as in [13]. Consider the symmetric difference \( X \oplus Y \), where \( X \oplus Y = (X - Y) \cup (Y - X) \). \( X \oplus Y \) is a disjoint collection of paths in \( G \) including closed cycles, each of which has edges that belong to \( X \) and \( Y \) alternately. Suppose that we have fixed some arbitrary ordering on all simple paths in \( G \), and designate a “start vertex” to each of the paths, which is arbitrary if the path is a closed cycle but must be an endpoint otherwise. This gives a unique ordering \( P_1, P_2, \ldots, P_m \) on the paths appearing in \( X \oplus Y \). The canonical path from \( X \) to \( Y \) involves “unwinding” each of the \( P_i \) in turn as follows. We need to consider two cases:
(i) \(P_i\) is not a cycle. Let \(P_i\) consist of the sequence \((v_0, v_1, \ldots, v_l)\) of vertices with the start vertex \(v_0\). If \((v_0, v_1) \in Y\), perform a sequence of switching moves replacing \((v_2j+1, v_2j+2)\) by \((v_2j, v_2j+1)\) for \(j = 0, 1, \ldots\), and finish with an addition move if \(l\) is odd. If \((v_0, v_1) \in X\), remove \((v_0, v_1)\) and proceed as before for the reduced path \((v_1, \ldots, v_l)\).

(ii) \(P_i\) is a cycle. Let \(P_i\) consist of the sequence \((v_0, v_1, \ldots, v_{2l+1})\) of vertices, for \(l \geq 1\), where \(v_0\) is the start vertex, and \((v_{2j}, v_{2j+1}) \in X\) for \(j = 0, \ldots, l\), with remaining edges belonging to \(Y\). We first remove the edge \((v_{2l}, v_{2l+1})\). Now we are left with an open path \(O\) with endpoints \(v_0, v_1\), with the start vertex \(v_k\) of \(O\), for \(k \in \{0, 1\}\). Then we unwind \(O\) as in (i) above but treating \(v_{1-k}\) as the start vertex to identify that it was a cycle.

Let \(t\) be an arbitrary edge in the Markov chain \(M\), i.e., a transition from \(\omega\) to \(\omega' \neq \omega\). Let \(cp(t) = \{(X, Y) : \gamma_{XY} \ni t\}\) be the set of canonical paths that use \(t\). We define a function \(\eta_t : cp(t) \rightarrow \Omega\) as in [13],

\[
\eta_t(X, Y) = \begin{cases} 
X \oplus Y \oplus (\omega \cup \omega') - e_{XY}, & \text{if } t \text{ is a switch move and the current path is a cycle;} \\
X \oplus Y \oplus (\omega \cup \omega'), & \text{otherwise,}
\end{cases}
\]

where \(e_{XY}\) is the edge in \(X\) adjacent to the start vertex that was removed first in (ii) above. \(\eta_t(X, Y)\) is always a matching in \(G\) and \(\eta_t\) is injective as shown in [13]. Notice that the bipartite graph \(G\) considered here is a subset of the graphs considered in [13] so the arguments about \(\eta_t\) can be directly applied here.

Notice that

\[
Q(t) = Q(\omega, \omega') = \pi(\omega)P(\omega, \omega') = \frac{1}{2|E|} \min\{\pi(\omega), \pi(\omega')\}.
\]  

(32)

Next, we bound \(\pi(X)\pi(Y)\) and we need to consider four cases:

(i) \(t\) is a deletion move. We have \(\omega' = \omega - e\) and \(\eta_t(X, Y) = X \oplus Y \oplus (\omega \cup \omega')\). Since \(\omega \cup \eta_t(X, Y)\) and \(X \cup Y\) are identical when viewed as multisets,

\[
\pi(X)\pi(Y) = \pi(\omega)\pi(\eta_t(X, Y)) = \frac{2|E|Q(t)}{\min\{\pi(\omega), \pi(\omega')\}} \pi(\omega)\pi(\eta_t(X, Y))
\]

\[
= 2|E|Q(t) \max\left\{1, \frac{\pi(\omega)}{\pi(\omega')}\right\} \pi(\eta_t(X, Y)) \leq 2R|E|Q(t)\pi(\eta_t(X, Y)),
\]

where we used the identity (32) in the second equality and Lemma [1] for the last inequality.

(ii) \(t\) is an addition move. We have \(\omega' = \omega + e\) and \(\eta_t(X, Y) = X \oplus Y \oplus (\omega \cup \omega')\). Since \(\omega \cup \eta_t(X, Y)\) and \(X \cup Y\) are identical when viewed as multisets, using the arguments from (i),

\[
\pi(X)\pi(Y) \leq 2R|E|Q(t)\pi(\eta_t(X, Y)).
\]
(iii) $t$ is a switch move and the current path is a cycle. Suppose $\omega' = \omega + e - e'$. Let $\omega_1 = \omega + e$. Then $\omega' = \omega_1 - e'$. Since $\frac{\pi(\omega)}{\pi(\omega')} = \frac{\pi(\omega_1)}{\pi(\omega)} \frac{\pi(\omega)}{\pi(\omega')}$, by Lemma 1, $\frac{\pi(\omega)}{\pi(\omega')} \leq CD \leq R^2$. Since $\eta_\ell(X, Y) = X \oplus Y \oplus (\omega \cup \omega') - e_{XY}$, the multisets $\omega \cup \eta_\ell(X, Y)$ differs from $X \cup Y$ only in that $e$ and $e_{XY}$ are missing from it. Hence, by Lemma 1,

$$\sum_{\gamma_{XY} \ni t} \pi(X)\pi(Y) \leq C^2 \pi(\omega)\pi(\eta(X, Y)) = 2C^2|E|Q(t) \max \left\{ 1, \frac{\pi(\omega)}{\pi(\omega')} \right\} \pi(\eta(X, Y))$$

$$\leq 2R^4|E|Q(t)\pi(\eta(X, Y)).$$

(iv) $t$ is a switch move and the current path is not a cycle. This case is similar to (iii) but the multisets $\omega \cup \eta_\ell(X, Y)$ differs from $X \cup Y$ only in that $e$ is missing from it. Hence, by Lemma 1,

$$\pi(X)\pi(Y) \leq C\pi(\omega)\pi(\eta(X, Y)) = 2C|E|Q(t) \max \left\{ 1, \frac{\pi(\omega)}{\pi(\omega')} \right\} \pi(\eta(X, Y))$$

$$\leq 2R^4|E|Q(t)\pi(\eta(X, Y)).$$

In summary, we have, in all cases, $\pi(X)\pi(Y) \leq 2R^4|E|Q(t)\pi(\eta(X, Y))$. Thus, for any transition $t$,

$$\frac{1}{Q(t)} \sum_{\gamma_{XY} \ni t} \pi(X)\pi(Y)|\gamma_{XY} | \leq 2R^4|E| \sum_{\gamma_{XY} \ni t} \pi(\eta(X, Y))|\gamma_{XY} |$$

$$\leq 4R^4K|E| \sum_{\gamma_{XY} \ni t} \pi(\eta(X, Y))$$

$$\leq 4R^4K|E| \leq 4R^4K^2N$$

where the second inequality follows from the fact that the length of any canonical path is bounded by $2K$, the third equality is due to the fact that $\eta_\ell$ is injective and $\pi$ is a probability distribution, and the last inequality follows from $|E| \leq KN$. Hence, $\bar{\rho} \leq 4R^4K^2N$. \]

We now prove Theorem 2. $M$ is a finite, reversible, ergodic Markov chain with loop probabilities $P(\omega, \omega) \geq \frac{1}{2}$ for all states $\omega$ (see Section IV-C). Hence, by Theorem 1 we know

$$\tau(\epsilon) \leq \bar{\rho}(\log \pi(\omega)^{-1} + \log \epsilon^{-1}).$$

The upper bound for $\bar{\rho}$ is computed from Lemma 2. Now we just need to find the upper bound for $\pi(\omega)^{-1}$. The normalizing constant in (27) is

$$Z = \sum_{\omega \in \Omega} \left( \prod_{i=0}^{\lceil \pi(\omega)/p_d \rceil} \left[ (1 - p_d)^{K - \lceil \pi(\omega)/p_d \rceil} \prod_{(u, v) \in \omega} \hat{\pi}^\omega(u|y_{1:t-1}) \right] \right) \cdot (34)$$

Hence,

$$Z \leq \sum_{\omega \in \Omega} m_1^K m_3(K, N) = m_1^K m_3(K, N)|\Omega|$$

$$\leq m_1^K m_3(K, N) \sum_{k=0}^K \binom{K}{k} \frac{N!}{(N-k)!} \leq m_1^K m_3(K, N)(K+1)!N!,$$
For any \( Z \), \( \bar{\mu}_{m_c} \) so
\[
\frac{1}{\pi(\omega)} \leq \frac{Z}{m_2^K m_4(K, N)} \leq \left( \frac{m_1}{m_2} \right)^K \frac{m_3(K, N)}{m_4(K, N)} (K + 1)!N!.
\]
Hence,
\[
\log \frac{1}{\pi(\omega)} \leq \log \left( \frac{m_1}{m_2} \right)^K \frac{m_3(K, N)}{m_4(K, N)} (K + 1)!N! \equiv m_0(K, N).
\]
Putting all together, we have, for all initial state \( \omega \in \Omega \), \( \tau(\epsilon) \leq 4R_1^4K^2N(m_0(K, N) + \log \epsilon^{-1}) \).

**B. Proof of Theorem 3**

To prove Theorem 3 we apply the techniques developed to prove Lemma 3 in \([41]\) to our problem. Let \( \beta_{\epsilon_2} = \{(j, k): \beta_{jk} \geq \epsilon_2\} \). For now, assume \( (j, k) \in \beta_{\epsilon_2} \), i.e., \( \beta_{jk} \geq \epsilon_2 \). Let \( X_{jk}(\omega) = I((\hat{y}^k, y^j) \in \omega) \) where \( I \) is an indicator function. Notice that \( \mathbb{E}_\pi(X_{jk}) = \pi(\omega_{jk}) = \beta_{jk} \), where \( \omega_{jk} = \{\omega \in \Omega: (y^j, k) \in \omega\} \). Since \( \|p - \pi\|_W \leq \epsilon \) and \( \epsilon \leq \epsilon_1 \epsilon_2/8 \),
\[
|p(\omega_{jk}) - \pi(\omega_{jk})| \leq \epsilon \leq \frac{\epsilon_1 \pi(\omega_{jk})}{8}
\tag{35}
\]
Let \( \bar{\beta}_{jk} = \frac{1}{s} \sum_{i=1}^s X_{jk}(\omega_i) \) be the sample mean of \( s \) samples from \( p \). Then \( \mathbb{E}(\bar{\beta}_{jk}) = p(\omega_{jk}) \) and \( \mathbb{V}ar(\bar{\beta}_{jk}) = \frac{1}{s} \mathbb{V}ar_p(X_{jk}) \). By Chebyshev’s inequality,
\[
P\left(|\bar{\beta}_{jk} - p(\omega_{jk})| > \frac{\epsilon_1}{3} p(\omega_{jk}) \right) \leq \frac{9}{\epsilon_1^2} \mathbb{V}ar_p(X_{jk}) \tag{36}
\]
Now if \( |\bar{\beta}_{jk} - p(\omega_{jk})| \leq \frac{\epsilon_1}{3} p(\omega_{jk}) \), from (35),
\[
|\bar{\beta}_{jk} - \pi(\omega_{jk})| \leq |\bar{\beta}_{jk} - p(\omega_{jk})| + |p(\omega_{jk}) - \pi(\omega_{jk})|
\leq \frac{\epsilon_1}{3} p(\omega_{jk}) + \frac{\epsilon_1}{8} \pi(\omega_{jk})
\leq \frac{\epsilon_1}{3} \left(1 + \frac{\epsilon_1}{8} \right) \pi(\omega_{jk}) + \frac{\epsilon_1}{8} \pi(\omega_{jk})
\leq \frac{\epsilon_1}{2} \pi(\omega_{jk})
\tag{37}
\]
and \( \bar{\beta}_{jk} \) estimates \( \pi(\omega_{jk}) \) within ratio \( 1 + \epsilon_1 \).

Now let us bound the difference between \( \mathbb{V}ar_\pi(X_{jk}) \) and \( \mathbb{V}ar_p(X_{jk}) \). Notice that \( \mathbb{V}ar_p(X_{jk}) = \sum_{\omega \in \Omega} p(\omega) X_{jk}(\omega)^2 - (\mathbb{E}_p X_{jk})^2 \) and \( \mathbb{V}ar_\pi(X_{jk}) = \sum_{\omega \in \Omega} \pi(\omega) X_{jk}(\omega)^2 - (\mathbb{E}_\pi X_{jk})^2 \).
\[
|\mathbb{V}ar_p(X_{jk}) - \mathbb{V}ar_\pi(X_{jk})| = \left| \sum_{\omega \in \Omega} X_{jk}(\omega)^2 (p(\omega) - \pi(\omega)) + (\mathbb{E}_\pi X_{jk})^2 - (\mathbb{E}_p X_{jk})^2 \right|
\leq \left| \sum_{\omega \in \Omega} X_{jk}(\omega)^2 (p(\omega) - \pi(\omega)) \right| + \left| (\mathbb{E}_\pi X_{jk})^2 - (\mathbb{E}_p X_{jk})^2 \right|.
\tag{38}
Since $X_{jk}(\omega) \leq 1$,

$$\left| \sum_{\omega \in \Omega} X_{jk}(\omega)^2 (p(\omega) - \pi(\omega)) \right| \leq \left| \sum_{\omega \in \Omega} p(\omega) - \pi(\omega) \right| \leq \epsilon. \quad (39)$$

On the other hand,

$$|\langle \mathbb{E}_\pi X_{jk} \rangle^2 - \langle \mathbb{E}_p X_{jk} \rangle^2| = |\langle \mathbb{E}_\pi X_{jk} + \mathbb{E}_p X_{jk} \rangle (\mathbb{E}_\pi X_{jk} - \mathbb{E}_p X_{jk})| \leq 2 |\mathbb{E}_\pi X_{jk} - \mathbb{E}_p X_{jk}| \leq 2 \sum_{\omega \in \Omega} \pi(\omega) - p(\omega) \leq 2\epsilon. \quad (40)$$

Using (39) and (40) in (38), we have

$$|\text{Var}_p(X_{jk}) - \text{Var}_\pi(X_{jk})| \leq 3\epsilon \leq \frac{3\epsilon_1\pi(\omega_{jk})}{8}, \quad (41)$$

where the last inequality is due to the condition $\epsilon \leq \epsilon_1\epsilon_2/8$ and $\pi(\omega_{jk}) \geq \epsilon_2$.

Since $\epsilon_1 < 1$ and $\text{Var}_\pi(X_{jk}) \leq \pi(\omega_{jk})$, we find the following bound using (35) and (41):

$$\frac{\text{Var}_p(X_{jk})}{p(\omega_{jk})^2} \leq \frac{\text{Var}_\pi(X_{jk}) + \frac{3}{8}\pi(\omega_{jk})}{(\frac{3}{8}\pi(\omega_{jk}))^2} \leq \frac{2}{\pi(\omega_{jk})}. \quad (42)$$

Hence, by choosing $s = 72\epsilon_1^{-2}\epsilon_2^{-1}$ and using (36) and (42), $P(\|\bar{\beta}_{jk} - p(\omega_{jk})\| > \epsilon_2 p(\omega_{jk})) \leq \frac{1}{4}$, that is, $\bar{\beta}_{jk}$ estimates $\pi(\omega_{jk})$ within ratio $1 + \epsilon_1$ with probability at least $3/4$.

To make the analysis easier, we assume a sampling technique which is slightly different from Algorithm [1]. We consider repeating the above experiment by an odd number $t$ times, independently. Let $\hat{\beta}_{jk}$ be the median of the resulting $t$ values of $\bar{\beta}_{jk}$. From above, the probability that $\hat{\beta}_{jk}$ fails to approximate $\beta_{jk}$ within ratio $1 + \epsilon_1$ is at most

$$\sum_{i=(t+1)/2}^{t} \binom{t}{i} \left( \frac{1}{4} \right)^i \left( \frac{3}{4} \right)^{t-i} \leq \left( \frac{1}{4} \right)^{t/2} \left( \frac{3}{4} \right)^{t/2} \sum_{i=(t+1)/2}^{t} \binom{t}{i} \leq \left( \frac{3}{16} \right)^{t/2} 2^t = \left( \frac{3}{4} \right)^{t/2}.$$ 

Now let $t = 7\lceil \log \eta^{-1} \rceil$, then

$$\left( \frac{3}{4} \right)^{t/2} \leq \left( \frac{3}{4} \right)^{3.5\lceil \log \eta^{-1} \rceil} \leq \eta^{3.5\log(4/3)} \leq \eta.$$

Hence, with a total of $st = 504\epsilon_1^{-2}\epsilon_2^{-1}\lceil \log \eta^{-1} \rceil$ samples, $\hat{\beta}_{jk}$ estimates $\pi(\omega_{jk})$ within ratio $1 + \epsilon_1$ with probability at least $1 - \eta$ for $\beta_{jk} \geq \epsilon_2$.

Now consider $\beta_{jk}$ that are smaller than $\epsilon_2$. With probability at least $1 - \eta$, for $(j, k) \in \beta_{\epsilon_2}$, $(1 - \epsilon_1)\beta_{jk} \leq \hat{\beta}_{jk} \leq (1 + \epsilon_1)\beta_{jk}$. So if $\hat{\beta}_{jk} \geq (1 + \epsilon_1)\epsilon_2$, we must have $(j, k) \in \beta_{\epsilon_2}$. Hence, $\hat{\beta}_{jk} \leq (1 + \epsilon_1)\epsilon_2$ or $|\hat{\beta}_{jk} - \beta_{jk}| \leq (1 + \epsilon_1)\epsilon_2$ for $\beta_{jk} < \epsilon_2$. 

C. Proof of Theorem

Lemma 3: Suppose that \(0 < p_z, p_d < 1\) and \(\lambda_b, \lambda_f > 0\). If \(\zeta(d) > 0\), for all \(d \in \{1, \ldots, \bar{d}\}\), then the Markov chain \(\mathcal{M}\) is irreducible.

Proof: The birth and death moves are sufficient to illustrate the irreducibility of the chain. Since \(0 < p_z, p_d < 1\) and \(\lambda_b, \lambda_f > 0\), \(P(\omega | Y) > 0\) for all \(\omega \in \Omega\). Take an arbitrary partition \(\omega \in \Omega\), say \(\omega = \{\tau_0, \tau_1, \ldots, \tau_K\}\). Now consider the partition \(\omega' \in \Omega\), such that \(\omega' = \{\tau'_0\}\), i.e., \(\omega'\) assigns all observations as false alarms. Since \(\omega\) is arbitrary, the chain is irreducible if the chain can move from \(\omega'\) to \(\omega\) and from \(\omega\) to \(\omega'\).

For the move from \(\omega'\) to \(\omega\), consider \(K\) consecutive birth moves: \(\omega_0 = \omega', \omega_1 = \{\{\tau'_0 \setminus \tau_1\}, \tau_1\}, \ldots, \omega_K = \{\tau_0 \setminus \{\cup_{i=1}^K \tau_i\}\}, \tau_1, \ldots, \tau_K\} = \omega\). Since \(\omega \in \Omega\), all tracks \(\tau_k\) are legal, i.e., \(\tau_k\) satisfies the constraints described in Section II-B and, for \(i = 1, \ldots, |\tau_k| - 1, \tau_k(t_i+1) \in L(\tau_k(t_i), t_i, d)\) for \(1 \leq d = t_{i+1} - t_i \leq \bar{d}\). Thus, \(\omega_k \in \Omega\) for all \(k\). Because \(\zeta(d) > 0\) and all tracks \(\tau_k\) are legal, the probability of proposing \(\tau_k\) at \(\omega_{k-1}\) by the birth move is positive and \(q(\omega_k, \omega_{k+1}) > 0\). For the move from \(\omega\) to \(\omega'\), consider \(K\) consecutive death moves: \(\omega_K = \omega, \omega_{K-1}, \ldots, \omega_0 = \omega'\). The probability of removing the track \(\tau_k\) at \(\omega_k\) by the death move is positive and \(q(\omega_{k+1}, \omega_k) > 0\). Since \(P(\omega_k | Y) > 0\) for all \(k\), the chain can move from \(\omega'\) to \(\omega\) and from \(\omega\) to \(\omega'\). Hence, the chain is irreducible.

From Lemma 3, \(\mathcal{M}\) is irreducible. \(\mathcal{M}\) is aperiodic since there is always a positive probability of staying at the current state in the track update move. Now the transitions described in Algorithm 3 satisfy the detailed balance condition since it uses the Metropolis-Hastings kernel \(\Pi\). Hence, by the ergodic theorem \([34]\), the chain converges to its stationary distribution \(\pi(\omega)\) almost surely and \(\hat{X} \rightarrow \mathbb{E}_\pi X\) as \(n_{mc} \rightarrow \infty\).
